Dedicated

To my beloved father Mr. Murad Ali Khan

&

My kids,

Ibraheem Khan & Musa Khan

ACKNOWLEDGMENTS

First of all thanks to ALLAH, the most merciful and beneficent, Who gave me the strength and power to complete my thesis with great interest and well on time.

I am highly thankful to the Department of Chemical Engineering, King Fahad University of Petroleum & Minerals (KFUPM), Saudi Arabia for awarding me Ph.D scholarship. I am highly thankful to my parental institute i.e. Department of Chemical Engineering, University of Engineering & Technology (UET) Peshawar for their support and paid study leave, to pursue my Ph.D.

I express sincere thanks to my advisor, Prof. Mamdouh A. Al-Harhi for his technical support, kind supervision and continuous guidance in my research. I am also very thankful for my committee members; Prof. Mohamed B. Amin, Dr. Mohammed S.Ba-Shammakh, Dr. Mohammad M. Hossain and Dr. Shaikh A. Razzak for their valuable and helpful suggestions.

An acknowledgment would not be complete without appreciating my parents and family for their encouragement, motivation and praying continuously for my successful Ph.D completion.

Finally, I would also like to present my acknowledgments to my university colleagues and close-friends especially Muhammad Yasir Khan, Muhammad Safdar Khan Afridi, Dr. Muhammad Sajid, Dr. Umer Mehmood, Farrukh Shehzad and Murad Ali who continuously motivate me in achieving my goals.

ABSTRACT

Full Name : MUHAMMAD DAUD

Thesis Title : *[EFFECT OF NANO FILLERS ON THE PRODUCTION AND PROPERTIES OF LLDPE USING IN-SITU POLYMERIZATION]*

Major Field : [CHEMICAL ENGINEERING]

Date of Degree : [December, 2016]

Linear low density polyethylene (LLDPE) was synthesized using in-situ polymerization of ethylene with various alpha olefins (comonomers). Zirconocene/MAO was used as catalyst/cocatalyst complex. The comonomers used under study were 1-hexene, 1-octene, and 1-decene. In this study, the effect of comonomers on the catalytic activity, melting temperature (T_m), degree of crystallinity (DOC), melt crystallization behavior and lamellar thickness distribution (LTD) were evaluated. A higher catalytic activity was recorded in the presence comonomers. Further, the comonomers have added more short chain branching (SCB) to the copolymers, which corresponds to lower DOC and T_m . The Mo crystallization model perfectly explained the crystallization behavior of the copolymers for all cooling rates under study. The modified Gibbs-Thomson equation was utilized to observe the melting behaviors and LTD of the copolymers. Moreover, the activation energies (E_A) were calculated using Kissinger method. The 1-hexene comonomer exhibited the lowest E_A . Overall, crystallization was found, to be more effected by the degree of branching rather than the comonomer type.

In another study, LLDPE nanocomposites were synthesized in the presence of nano titania doped with 1 % (TiO_2/Mn), used as a drop-in nanofiller. The comonomer selected for this study was 1-hexene, based on our previous findings. The nanofiller added more SCB to the polymer backbone and as result decreased the DOC and T_m . The non-isothermal crystallization behavior of the synthesized polymer nanocomposites were studied by Ozawa and Mo models. Additionally, the E_A of the nanocomposites were calculated using Kissinger method. An increased E_A profiles were observed, confirming a slower crystallization process in the presence of nano filler.

Further, graphene/layered double hydroxides (G/LDHs) hybrid nanofillers were synthesized by co-precipitation technique and were successfully characterized using different characterization techniques. The hybrid G/LDHs based ethylene-co-1-hexene nanocomposites were synthesized using in-situ polymerization. The activity of the zirconocene catalyst was boosted in the presence of hybrid nanofillers. Moreover, the synthesized polymer nanocomposites have shown improved thermal stability. E_A for the synthesized polymer nanocomposites were calculated using Friedman iso-conversional method. The G/LDHs based polymer nanocomposites have shown higher E_A (more thermal stability) compared to bare LDHs based nanocomposites, because of the superior thermal properties inherited by these hybrid nanofillers.

Keywords: Copolymers, Catalytic activity, Melt crystallization, Hybrid materials
Graphene/Layered double hydroxides nanocomposites

ملخص الرسالة

الاسم الكامل: محمد داؤود

عنوان الرسالة: تأثير المواد المالئة النانوية في تحسين انتاج وخصائص البولي اثيلين الخطي منخفض الكثافة باستخدام تقنية البلمرة في الموقع

التخصص: هندسة كيميائية

تاريخ الدرجة العلمية: ديسمبر 2016

في هذه الدراسة تم تصنيع البولي اثيلين الخطي منخفض الكثافة (LLDPE) باستخدام طريقة in-situ polymerization من الاثيلين وألfa الأوليفينات وقد استخدم zirconocene / MAO كمحفز معقد. تم استخدام جزيئات (comonomers) مختلفة مثل 1-hexene، 1-octene، و 1-decene. أيضا في هذه الدراسة تمت دراسة تأثير comonomers على نشاط المحفز، ودرجة حرارة الانصهار (T_m) ودرجة التبلور (DOC) و lamellar thickness distribution. وجود comonomers زاد من نشاط المحفز. وعلاوة على ذلك، عند اضافة نسب أعلى من comonomer تزداد التفرعات السلسلية القصيرة (SCB)، والتي أدت بدورها الى انخفاض درجة التبلور (DOC) ودرجة الانصهار. وأوضحت طريقة Mo بصورة جيدة سلوك بلورة comonomers عند درجات تبريد مختلفة. استخدمت معادلة Gibbs Thomson المعدلة لدراسة سلوك الانصهار و lamellar thickness distribution. تم حساب طاقات التنشيط باستخدام طريقة Kissinger. أوضحت نتائج الدراسة ان 1-هيكسين comonomer له طاقة التنشيط الأقل وان عملية التبلور تعتمد بشكل اكبر على درجة التفرع بدلا من نوع comonomer.

وعلاوة على ذلك، تم في هذه الدراسة تصنيع البولي اثيلين الخطي منخفض الكثافة (LLDPE) باستخدام 1 % من المغنيز المطعم باوكسيد التيتانيوم (Mn/TiO_2) كمادة مالئة نانوية. تم اختيار 1-هيكسين (comonomer) لهذه الدراسة استنادا إلى النتائج السابقة التي توصلنا إليها. أدى اضافة المادة المالئة النانوية الى زيادة SCB وتقليل DOC ودرجة الانصهار. وايضا تم دراسة عملية التبلور (non-isothermal) للمواد المحضرة باستخدام النماذج المقترحة من قبل Ozawa و Mo. بالإضافة إلى ذلك، تم حساب طاقة التنشيط (E_A) للبوليمر المتناهي الصغر

باستخدام طريقة Kissinger. وظهرت نتائج الدراسة الى وجود زيادة في طاقة التنشيط (E_A) ، مؤكدا ابطاء عملية التبلور بسبب وجود المادة المألئة النانوية.

تم ايضا في هذه الدراسة تصنيع مادة مألئة نانوية هجينة بنجاح من الجرافين / هيدروكسيدات مزدوجة الطبقات (G/LDHs) بواسطة تقنية co-precipitation. واستخدمت هذه المألئة النانومترية الهجينة كمادة مألئة في بلورة الاثيلين و 1-هيكسين . و أظهرت نتائج الدراسة وجود زيادة كبيرة في نشاط الحفاز (zirconocene) بسبب وجود هذه المألئة النانومترية الهجينة. وأظهرت نتائج البحث كذلك أن البوليمرات النانوية المحضرة لها استقرار حراري افضل . تم حساب طاقة التنشيط للبوليمرات المحضرة باستخدام طريقة iso-conversional Friedman. وقد اوضحت نتائج بأن البوليمرات النانوية المحضرة باستخدام G/LDHs لها طاقة تنشيط أعلى من البوليمرات النانوية المحضرة باستخدام LDHs بسبب خواصها الحرارية الفائقة.

كلمات البحث: البوليمرات المشتركة، النشاط التحفيزي، تذويب التبلور، الجرافين / هيدروأكسيدات الطبقات المزدوجة النانوية، المواد الهجينة. |

CHAPTER 1

INTRODUCTION

1.1 Polyethylene synthesis

Single site metallocene complexes have gained great interest in the synthesis of polyethylene (PE). The complexes have opened new avenues for synthesizing polymers, having high catalytic activities, high comonomer incorporation, controlled polymer tacticity, efficient microstructure control and chemical composition distribution (CCD). An increased global demand has been noted during the last few decades for the polyethylene (PE) and especially for its derivatives that include high density polyethylene (HDPE), low density polyethylene (LDPE), and linear-low density polyethylene (LLDPE). Among them, the LLDPE has a very prominent demand because of its special applications such as food packaging, shopping bags and beverages bottling, etc. The LLDPE's synthesized with metallocene complexes exhibit several attractive properties depending on the nature and concentration of comonomer used during polymerization reactions [1,2].

1.2 Effect of comonomer

Commercially used comonomers mainly include α -olefins i.e. 1-hexene, 1-octene, and 1-decene. The comonomer has a noticeable effect on: catalytic activity, degree of

crystallinity (DOC), melting temperature (T_m) and several other properties. The catalytic activity of the higher α -olefins (1-decene) exhibit higher catalytic activity compared to 1-octene and 1-hexene under the same conditions of pressure, temperature and comonomer composition for polymerization reaction. However a contradictory results were observed by Mingkwan et al. (2011) by recording a slight decrease in catalytic activity while using 1-decene comonomer compared to 1-octene, due to steric hindrance effect caused by 1-decene comonomer. Higher amorphous contents were noted due to increase of comonomer ratio in the feed and vice versa [1].

1.3 Polymer nanocomposites

In order to enhance the mechanical properties, dielectric properties, heat resistance properties and strength of the PE, various nanofillers can be utilized either by melt blending or by *in-situ* polymerization. During the production of polymer nanocomposites the nanofiller remains in a discontinuous phase in the entire polymer matrix thus enabling them to have better properties than the unmodified polymer. The thus produced nanocomposites have high stiffness and tensile strength. These nanofillers also have high degree of interfacial interaction (due to their nano size) which provides high surface area compared to conventional fillers. Several nano fillers including; Titania (TiO_2), graphene, layered double hydroxides (LDHs) and hybrids of G/LDHs are studied in this thesis. Every nanofiller impart their own special characteristics to the polymer nanocomposites e.g. TiO_2 is the most promising inorganic nanofiller because of its versatile properties, such as unique optical properties, anti-static behavior (used as antibacterial agent), and interesting photo catalytic properties. TiO_2 boosts the catalytic performance of metallocene

catalyst and increases the activation energies. Similarly, the presence of graphene in the polymer nanocomposites made them mechanically strong and thermally more stable [1–4].

1.4 Melt crystallization

The polymer crystallization is an important phase transition process. In fact, the rate of crystallization and the degree of crystallinity are key factors in polymer processing. The comonomer composition and nanofiller both can affect the crystallization kinetics as well. The crystallization kinetics are very important, not only for polymer processing but also for obtaining the desired characteristics. The non-isothermal crystallization kinetics usually have more importance than the isothermal kinetics due to its practical operations and implementation in the industry. These non-isothermal melt studies successfully cover a wide range of kinetic models including Jeizorny, Ozawa and Mo models for the PE and their nanocomposites [2,5].

1.5 Thesis Summary

This summary section highlights the summary of each chapter. Each chapter is discussed in the manuscript format.

Chapter-2 described the general literature related to the production of PE. Further, the importance of LLDPE and metallocene based complexes for LLDPE synthesis were discussed briefly. The chapter also includes the literature review for PE nanocomposites and their applications.

Chapter-3 described the impact of branching and comonomer type on the crystallization kinetics, lamellar thickness distribution and activity of zirconocene catalyst. The comonomers used for this study were: 1-hexene, 1-octene and 1-decene. The *in-situ* polymerization were adopted for the polymer synthesis. Initially equal amounts of each of the comonomer were added to the ethylene polymerization to analyze the comonomer type upon catalytic activity and non-isothermal crystallization kinetics of the synthesized copolymers. The comonomer amount in the reaction greatly influences the final product properties. The activation energies (E_A) were calculated using the Kissinger method and found to be lower for the 1-hexene comonomer, which empowers the 1-hexene copolymer to crystallize relatively easy as compared to other copolymers.

Chapter-4 described the synthesis of LLDPE using 1-hexene as a comonomer by *in-situ* polymerization in the presence of nano TiO_2 . The catalytic activities and comonomer incorporation was significantly increased by the addition of nano- TiO_2 . The crystallization analysis fractionation (CRYSTAF) profiles has revealed that the microstructure of the copolymers were altered due to TiO_2 nanofiller. The Mo-model perfectly explains the non-isothermal crystallization behavior of the copolymers. The activation energy (E_A) required for the polymerization process was found to be increased with the TiO_2 addition, showing difficulty in the crystallization process.

Chapter-5 described the various synthesis routes adopted for the hybrid graphene/layered double hydroxides (G/LDHs) nanocomposties. The chapter also summarized applications of hybrid materials in various arenas such as supercapacitors, catalysis and nanofillers for polymer nanocomposites. Further, future challenges to continuous mass production, uniform particulated sized were also discussed in detail.

Chapter-6 described the synthesis of G/MgAl hybrid nanofiller using co-precipitation method. The nanofiller was then characterized using different characterization techniques. The synthesized nanofiller was then used as drop-in filler for LLDPE synthesis. This chapter also studied the effect of catalytic activity, crystallinity and degradational kinetics of the as-synthesized LLDPE nanocomposites due the addition of G/MgAl nanofiller.

Chapter-7 described the brief summary of the conclusion and recommendations along with the research outcomes in the form of research publications obtained from this thesis.

CHAPTER 2

LITERATURE REVIEW AND BACKGROUND

2.1 Ethylene polymerization

Polyethylene (PE) is a widely used polymer because of its low production cost and remarkable properties thus making them a favorite product to be used in variety of application such as toys, food packaging, home appliances *etc.* [1]. A huge increase in the production trends of PE has been noted over the last few decades due to its high demand in global plastic consumption [2].

PE are essentially be synthesize by ethylene polymerization/copolymerization with α -olefins (comonomers) including 1-hexene, 1-octene and 1-octene *etc.* [3]. The PEs are sub-categorized as high density PE (HDPE), low density PE (LDPE) and linear-low density PE (LLDPE) or sometimes called very-low density PE (VLDPE) illustrated in Figure 2-1 [1,4]. The short chain branching (SCB) and long chain branching (LCB) attached with ethylene backbone are the basis for the classification of PE. The differences between HDPE/LLDPE and LDPE are further summarized in Table 2-1.

Figure 2-1. Classification of PE on the basis of branching structure and densities range [1] with permission from John Wiley and Sons

Table 2-1. Sketch of differences between HDPE/LLDPE and LDPE [1]

HDPE/LLDPE	LDPE
Produced at relatively lower temperature and pressure by copolymerization of ethylene with α -olefin.	Produced by high temperature, high pressure process by polymerization of ethylene without any co-monomer.
Follow Co-ordination polymerization.	Free radical polymerization is involved in the production of LDPE.
SCB are the results of copolymerization of α -olefin.	LCB are formed due to polymer chain transfer reactions. SCB are the results of backbiting reactions.

2.2 Linear low density polyethylene (LLDPE)

Linear low density PE (LLDPE) is synthesized by the copolymerization of ethylene in the presence of comonomer. Commercially used comonomers for the production of LLDPE are α -olefin including 1-butene, 1-hexene and 1-octene [5,6]. The olefins or monomers coordinate with the catalyst active sites and get inserted to the growing polymer chain shown in Figure 2-2. The final copolymer chemical composition distribution (CCD) is highly dependent on different comonomer coordinations and insertion rates [4,7]. LLDPE is one of the most important emerging resins of PE not only because of their low production cost but also due to the properties that make them of remarkable interest to the consumers [8,9]. The most prominent applications of LLDPE including food packaging, shopping bags and beverages bottling, etc. [10]. The addition of the comonomer greatly affects the final product properties, including the catalytic activity, melting temperature, the microstructure of the end polymer and aslo effects the crystallization kinetics [6,11–13].

Figure 2-2. Structural design of LLDPE ethylene/1-hexene copolymer

2.3 High activity catalysts for LLDPE production

Single site (metallocene catalysts) or multiple sites (Ziegler-Natta or Phillips) catalysts are widely used for polymerization of HDPE and LLDPE. These catalysts are also known as coordination polymerization catalyst, since they polymerized the product through coordination polymerization [4,7]. The discovery of Ziegler-Natta (ZN) catalyst in the early 1950's was a major breakthrough to the polyolefin industry. The high catalytic activity and selectivity of ZN catalysts makes them favorite for the LLDPE production commercially [2,14]. Selection of process (gas phase, slurry & solution) and catalyst selection (Ziegler-Natta, Phillips or Metallocene) are the important parameters that influence the properties of PE and also control the economics of the system. But due to the single siteness of the metallocene catalyst, it is preferred over Ziegler Natta catalyst, as it gives uniform and narrow microstructure distribution for the copolymers [15,16]. The CCD greatly affects the properties of the copolymers, thus a fast and reliable quantitative technique is mandatory for CCD analysis rapidly [17,18].

2.4 Mettallocene catalyst/cocatalyst complex studies

The LLDPE synthesized with metallocene catalyst/cocatalyst complexes exhibit several attractive properties depending on the nature and concentration of comonomer used during polymerization reactions [19]. Kaminisky and his coworkers in 1998 suggested that, the methylaluminoxane (MAO) is more effective cocatalyst as compared to trimethylaluminium (TMA) while using metallocenes as a catalyst [11]. Further in his studies, he discovered that metallocene/MAO complex can be used to synthesized

LLDPE with high degree of microstructure control, uniform CCD, which cannot be possible to achieve while using the conventional heterogeneous Ziegler-Natta catalyst [20]. MAO is sometimes modified with glycol, ethers or polyethers to synthesized the LLDPE, these polymers have high melt flow index and better thermal processability [21]. The modified methylaluminoxane type 3 (MMAO) and activated modified methylaluminoxane (AMMAO) activators can preferably be used with metallocene catalysts for high yield of LLDPE [3,22–24]. Other activators/cocatalyst that are widely used for synthesis of LLDPE using metallocene catalyst includes; Borane type (polyisobutylaluminoxane and tris(pentafluorophenyl)borane) and Borates type (tetrakis(pentafluorophenyl) and Lithium tetrakis(pentafluorophenyl) borates) [25–28].

2.5 Polymer nanocomposites

In order to enhance the mechanical, electrical and heat resistance properties of the PE, various nano fillers are utilized either by melt blending or by *in-situ* polymerization [29,30]. During the production of polymer nanocomposites the nano filler remains in a discontinuous phase in the entire polymer matrix thus enabling them to have better properties than the unmodified polymer. The thus produced nanocomposites have high stiffness and tensile strength [31,32]. The nano fillers have a high degree of interfacial interaction (due to their nano size) which provides high surface area compared to conventional fillers [31]. Several nano fillers including SiO₂ [32–34], TiO₂ [29,30,35,36], Al₂O₃ [37], LDHs [38] and graphene [39] are widely studied in literature.

2.5.1 PE/TiO₂ nanocomposites

TiO₂ is the most promising inorganic nano filler because of its versatile properties, such as unique optical properties, anti-static behavior (used as antibacterial agent), and interesting photo catalytic properties [29,35]. A detail literature study of PE/TiO₂ are tabulated in Table 2-2.

Table 2-2. PE/TiO₂ Nanocomposites properties and applications

Authors	Study	Findings
Wang Z et al., 2005 [29]	Preparation and characterization of polyethylene/TiO ₂ nanocomposites.	Significant improvement in the impact strength and tensile strength of the polyethylene by the addition of filler by melt compounding.
Wathanyoo O. et al., 2010 [40]	Synthesis of LLDPE/TiO ₂ nanocomposites by <i>in-situ</i> polymerization with zirconocene/dMMAO catalyst.	The dMMAO is impregnated on TiO ₂ to get white powder of dMMAO/TiO ₂ . The catalytic activity is increased by four times as compared to rutile TiO ₂ .

<p>Kaleel A. et al., 2012 [30]</p>	<p>Effect of Mn doped-titania on the activity of metallocene catalyst by <i>in-situ</i> ethylene polymerization</p>	<p><i>In-situ</i> polymerization is the most promising technique to produce polymer nanocomposites with homogeneous distribution of the nanoparticles inside the polymer matrix. Polymerization temperature greatly effect catalytic activity. The filler addition has less effect on Tm. Doped titania has four folding effect on the catalytic activity.</p>
<p>Chaichana E. et al., 2012 [35]</p>	<p>LLDPE/TiO₂ nano composites produced from different crystallite sizes of TiO₂ via <i>in-situ</i> polymerization</p>	<p>Different nano crystallite sizes of TiO₂ influences the catalytic activity and comonomer incorporation in the polymer nano composites. Larger the crystallite size of the nano filler provided better catalytic activity while lesser comonomer incorporation and vice versa.</p>
<p>Daud M. et al., 2015 [41]</p>	<p>Non-Isothermal Crystallization Kinetics of LLDPE Prepared by In-Situ Polymerization in the Presence of Nano Titania.</p>	<p>Doped titania has drastic effect on the activity of the zirconocene catalyst by increasing the 1-hexene incorporation. The optimum dose of the nano filler is found to be 15mg. The activation energies facts revealed that the crystallization process get slower with filler addition. Mo</p>

		model perfectly explain the crystallization behavior of the copolymer.

2.5.2 PE/Graphene nanocomposites

Graphene is one of the new emerging carbon based material of the modern era with Sp² hybridized carbon atoms arranged in honey comb hexagonal structure. Thermal and mechanical properties of the polymers are dramatically enhanced even with low graphene content [42–44]. Detailed literatures of the effect of graphene on the PE nanocomposites are tabulated below in Table 2-3.

Table 2-3. Graphene/PE nanocomposites properties and applications

Authors	Study	Findings
Khanam PN. et al., 2015 [45]	Electrical Properties of Graphene Polymer Nanocomposites	Significant improvement in the electrical properties has been recorded with low dosages of graphene addition. The dispersion of graphene greatly influences the Polymer graphene nanocomposites electrical properties.
Farrukh S. et al., 2015 [46]	Synthesis, Characterization and Crystallization Kinetics of Nanocomposites Prepared by <i>in-situ</i> Polymerization of Ethylene and Graphene	Thermal and mechanical properties of the nanocomposites are greatly improved with graphene loading. Decrease catalytic activities and increase weight average molecular weight (M_w) is observed for the PE/Graphene nanocomposites.

Kuila T. et al., 2011 [47]	Effect of functionalized graphene on the physical properties of linear low density polyethylene nanocomposites	An increase in the dimension stability, crystallization temperature, storage modulus and thermal stability of the LLDPE/Dodecyl-amine-modified graphene nanocomposites were noted over neat LLDPE. However, the % crystallinity and oxygen/nitrogen permeability decreases.
Kim H. et al., 2010 [48]	Graphene/polyethylene nanocomposites: Effect of polyethylene functionalization and blending methods	Graphene/PE nanocomposites possess better mechanical and electrical properties but the effective dispersion of graphene is difficult to achieve. The LLDPE functionalized with amine and nitrile groups can uniformly disperse graphene nanosheets using solvent based melt blending. The unmodified LLDPE/graphene nanocomposites have higher electrical conductivity as compared to modified one.
Fim F. et al., 2012 [49]	Thermal, Electrical, and Mechanical Properties of Polyethylene–Graphene Nanocomposites Obtained by	Effective dispersion can be achieved using <i>in-situ</i> polymerization of PE using zirconocene and MAO complex. The onset degradation temperature of the nanocomposites is increased by 30°C for

	<i>in-Situ</i> Polymerization	20 weight percent. Percolation threshold is recorded at a loading of 8.4 weight percent of graphene. The glass transition temperature is increased from -111°C (neat PE) to -106 °C (6.6 wt. % of graphene loading).
Stürzel M. et al., 2012 [50]	Novel Graphene UHMWPE Nanocomposites Prepared by Polymerization Filling Using Single-Site Catalysts Supported on Functionalized Graphene Nanosheet Dispersions	UHMWPE is synthesized using <i>in-situ</i> polymerization filling having functionalized graphene as a support for MAO activated single site chromium (Cr1) catalyst. The complex gives excellent catalytic activities and morphological to the synthesized UHMWPE. The general safety and handling problems associated to the dispersion of graphene using the conventional PE/graphene nanocomposites can be much reduced using FG/MAO/Cr1 complex.

2.5.3 PE/LDHs Nanocomposites

On the other hand, layered double hydroxides (LDHs) have 2D highly tunable brucite-like lamellar crystal structure [51]. They are also commonly known as anionic clays with metallic hydroxides positive layers with charge neutralizer anions (Cl, NO₃, CO₃ etc.). The water associated within the lamellar geometry comes from the synthesis routes followed [52]. Like graphene, LDHs are also employed as nanofillers for the synthesis of polymer nanocomposites [53]. These LDHs based polymer nanocomposites have shown better thermal stability and flame retardancy [54,55]. PE/LDHs nanocomposites properties and applications literature is summarized in Table 2-4.

Table 2-4. PE/TiO₂ Nanocomposites properties and applications

Authors	Study	Findings
Wei Chen. and Baojun Qu. 2004 [56]	LLDPE/ZnAl LDH-exfoliated nanocomposites: effects of nanolayers on thermal and mechanical properties	The ZnAl LDHs were synthesized using Self-assembly technique. The NO ₃ anions were replaced with dodecyl sulfate (DS) through intercalation technique for better dispersion of nano LDHs in the polymer matrix. Polymer nanocomposites with 5 wt. % and 20 wt. % were synthesized by solution intercalation technique. The as-synthesized LLDPE/ZnAl nanocomposites has shown better thermal stability having corresponding activation energies as 94, 215 and 150 kJ mol ⁻¹ for control, 5 and 20 wt. % respectively. Also

		<p>the decomposition temperatures were recorded as 384, 440 and 426 °C respectively, at 30 % wt. loss was considered as reference. Further, the young modulus of 20 wt. % was increased by 59 % over control LLDPE. However, the strength and elongation at break slightly decreased due to decrease crystallinity.</p>
<p>Longchao Du. and Baojun Qu. 2004 [57]</p>	<p>Structural characterization and thermal oxidation properties of LLDPE/ MgAl-LDH nanocomposites</p>	<p>The MgAl LDHs were synthesized using co-precipitation method and was successfully characterized. The LLDPE/LDHs nanocomposites were fabricated using melt blending. The 10 wt. % nano blend has shown better thermal stability by enhancing the degradation temperatures up to 42 °C over control LDLPE at 40 wt. % loss analysis. These LLDPE/MgAl nanocomposites are exhibiting interesting fire retardant properties. Further, the charring process initiated by MgAl LDHs compels the blend to be slowly thermally oxidized in the temperature range of 200</p>

		to 320 °C.
Peng Ding. And Baojun Qu. 2006 [58]	Structure, Thermal Stability, and Photocrosslinking Characterization of HDPE/LDH Nanocomposites Synthesized by Melt-Intercalation	The co-precipitation synthesis route were followed for ZnAl LDHs. The organomodification of these LDHs were done using the DS. The ZnAl (DS) LDHs were used in 1, 5, 10 and 20 wt. % loading in HDPE. Approx. 40 °C increased were recorded in the decomposition temperature for 5 wt. loaded blend, when taking reference at 50 wt. % loss. Further, these LDHs have the tendency to absorb UV-irradiation and thus the gel contents of 20 wt. % blend at 2s exposure is 1.4 % compared to control HDPE (64.9). Moreover, the photo cross linking efficiency of HDPE/LDHs blends has shown significant decrease due to high uptake of UV light at higher LDHs loading.
Francis RC. et al., 2007 [59]	LDPE/MgAl layered double hydroxide nanocomposite: Thermal and flammability	The melt blend of LDPE/MgAl LDHs is fabricated using twin screw extruder. A 20 °C increased in the decomposition temperature were recorded with just 2.43 wt. % LDHs addition having a peak heat

	properties	<p>release rate (PHRR) value of 600 kW m^{-2}.</p> <p>The PHRR for virgin LDPE was recorded to be 800 kW m^{-2}. This reduction in PHRR corresponds to better flame retardant property of PE nanocomposites. Moreover, at high loading of LDHs (16 wt. %) the PHRR recorded was 300 kW m^{-2} with a 44 % reduction in total heat release (THR). Further, the burning rate of 16.2 wt. % has decreased from 33 to 22 mm/min. These results have shown that better flame retardant polymers can thus be fabricated using LDHs as nanofillers.</p>
Lei Ye. and Qianghua Wu. 2011 [60]	<p>Effects of an Intercalating Agent on the Morphology and Thermal and Flame-Retardant Properties of Low-Density Polyethylene/Layered Double Hydroxide Nanocomposites Prepared by Melt</p>	<p>Three types of anion intercalated MgAl LDHs were successfully synthesized by the authors. These anions include NO_3, dodecyl sulfate anion (DS) and stearate anion (SA). The LDPE/MgAl nanocomposites were synthesized using melt intercalation technique. A better dispersion and morphology can be achieved with MgAl-SA LDHs. Further, the thermal stability and fire retardancy of the PE nanocomposites obey the order as</p>

	Intercalation	PE/SA > PE/DS > PE/NO ₃ .
Jean CB. et al., 2016 [38]	Metallocene supported core @LDH catalysts for slurry phase ethylene polymerization	The slurry phase polymerization was conducted with metallocene catalysts supported on hybrids of silica@LDHs and zeolite@LDHs using MAO as a cocatalyst. The synergistic effect of LDHs has significantly affected the catalytic activity both in temperature and time domain. As a result of hybridization with LDHs, the activity of the metallocene catalyst has increased up to three times by supporting the accessibility, stability of metallocene based catalysts.

ABSTRACT

The effect of comonomer and branching on the melt crystallization and lamellar thickness distribution was studied for ethylene and 1-alkene copolymers. The comonomers used in this study are 1-hexene, 1-octene, and 1-decene. A notable influence of the comonomer ratio in the feed was observed on the crystallization and melting behavior. The Ozawa and Mo models were found suitable for these copolymers. However, variation of relative crystallinity at different heating rates preferred the Mo method over the Ozawa method. The melting behavior and lamellar thickness distribution of the copolymers were analyzed by the help of modified Gibbs-Thomson equation. The activation energies (E_A) for the melt crystallization were calculated using the Kissinger method. It was observed that 1-hexene comonomer exhibits lower E_A , indicating an easier crystallization process as compared to other comonomers used. Overall, crystallization was found to be more influenced by the degree of branching rather than the comonomer type.

Keywords: metallocene catalyst, crystallization kinetics, copolymer, lamellar thickness distribution.

3.1 INTRODUCTION

Single site metallocene complexes have gained great interest in the synthesis of polyethylene (PE). The complexes have opened new paths for synthesizing polymer having high catalytic activities, high comonomer incorporation, controlled polymer tacticity, efficient microstructure control and chemical composition distribution (CCD) [1–4]. An increased global demand has been noted during the last few decades for the PE and especially for its derivatives that include high density polyethylene (HDPE), low density polyethylene (LDPE), and linear-low density polyethylene (LLDPE). LLDPE has very prominent demand because of its special applications such as food packaging, plastic bags, wraps, and pipes etc. [5,6]. The LLDPE synthesized with metallocene complexes exhibits several attractive properties depending on the nature and concentration of comonomer used during polymerization reactions [7–10]. PE and all its derivatives are semi crystalline in nature, and solidify easily during its crystallization. Since the addition of comonomer increases the amorphous contents in the copolymer, thus affecting the crystal structure and morphology and as a result the crystallization kinetics behavior is altered. Therefore, the knowledge of polymer crystallization kinetics and resulting degree of crystallinity are helping tools for its processing and desired characteristics [11,12]. Several studies have been done for better understanding of the concepts linked with isothermal and non-isothermal crystallization behavior of PE [13,14]. The non-isothermal crystallization kinetics has more practical significance over the isothermal kinetics study due to its industrial applications [15]. These non-isothermal melt studies successfully cover a wide range of kinetic models including Jeizorny, Ozawa and Mo models [16–18] for the HDPE, LDPE and LLDPE [14,19,20]. The modeling of

melting behaviors is utilized to study the lamellar thickness distribution (LTD) and average lamellar thickness for the PEs using modified Gibbs-Thomson (MGT) equation [21–23]. Adamu et al. studied the LTD and average lamellar thickness of the ethylene- α -olefin homo- and copolymers using metallocene complexes. It was found that the lamellar thickness of the homopolymer is much widely distributed than the copolymers; with a high weight average lamellar thickness (WALT) calculated using Flory and GT equations. This could be ascribed to the resulting decrease in longer lamellae by the butyl branching of the copolymer [24].

In this research work, in-situ polymerization of ethylene with variant amounts of α -olefins is performed using zirconocene and methyl aluminoxane (MAO) as catalyst/cocatalyst complex. The aim is to study the effect of branching and comonomer type on crystallization behavior, lamellar thickness distribution and activation energies (E_A). The crystallization kinetics and the quantitative effect of branching were analyzed by the Ozawa and Mo models. The LTD and mathematical correlation of WALT with the degree of crystallinity (DOC) was obtained using MGT equation. Activation energy (E_A) was evaluated using Kissinger method [25] and compared with all the samples.

3.2 EXPERIMENTAL

3.2.1 Chemical Reagents

All chemical reagents sensitive to oxygen were stored and manipulated in a glove box under nitrogen atmosphere. Zirconocene ($C_{10}H_{10}Cl_2Zr$) Bis(cyclopentadienyl zirconium (IV) dichloride) > 98 %, methyl aluminoxane (MAO), α -olefins (1-hexene, 1-octene, and

1-decene) and other solvents (toluene and methanol) were provided by the Sigma Aldrich Company and were used as received.

3.2.2 Polymerization Reaction

A Schlenk reactor was charged with 6 mg (20 μmol) of the zirconocene catalyst with subsequent addition of varying amount of α -olefins in 100 mL of solvent (toluene), inside the glove box. The reactor equipped with magnetic stirrer and recipe of the copolymer formation was air tightened using rubber septum and connected to the ethylene line and left for 5 min to get ethylene saturation. After saturation, the MAO was injected into the reactor to initiate the polymerization reaction for 25 minutes. The polymerization conditions were fixed for all reactions i.e. 303 K and 1.3 bar polymerization temperature and ethylene pressure respectively. After a total of 30 min. reaction time, the septum was then removed and the copolymer was quenched with acidified methanol (5 Vol %) for 45 min. The copolymer thus formed was filtered and dried for 24 hours in an oven set at 333 K [19]. The abbreviations used for the LLDPE in the current studies are: HEX-1, HEX-2, OCT-1, OCT-2, OCT-4, DEC-1, DEC-2 and DEC-4, whereas the HEX, OCT and DEC represented the comonomers used while the integers associated with them showed that the milliliters utilized of that particular comonomer in the copolymer synthesis.

3.2.3 Polymer Characterization

The melting and crystallization behavior of the copolymers were characterized by using a DSC Q-1000, TA instruments. The equipment was calibrated using Indium samples. The copolymers were analyzed using conventional heat-cool-heat cycle; at a heating rate of 10 K/min. Melting temperature (T_m) and DOC were recorded from the 2nd heating cycle. For the study of crystallization kinetics, the samples were first heated to 423 K and kept

isothermal for 3 min. to minimize the effect of thermal history [26,27]. The samples were then cooled down at variant cooling rates (β), i.e. 1, 2, 3, 5, 10, 20, and 30 K/min. For baseline and integration of the recorded scans, software (Universal Analysis 2000, TA Instruments) was used provided by the vendor.

Crystallization analysis fractionation (CRYSTAF) was utilized for finding the chemical composition distribution (CCD) of the synthesized copolymers (provided by Polymer Char Instrument model-200). The samples were first dissolved in 1, 2, 4 trichlorobenzene (TCB) at a concentration of 0.1 mg/mL at 423 K for 60 min. The dissolved copolymer was then allowed to cool at 0.1 K/min. passing through a dual wavelength infrared detector to determine the polymer being crystallized in the solution [28,29].

The comonomer incorporation was determined using carbon 13 nuclear magnetic resonance (^{13}C NMR). Approx. 70 to 80 mg of the copolymer was dissolved in TCB at 393 K in 5 mm standard NMR tube with 0.5 mL of deuterated benzene- d_6 (lock) [30]. The comonomer mole percentage was determined using ASTM method 5017-96 based on integration of peaks relative to main methylene resonance at 30.0 ppm on x-axis [31].

3.3 RESULTS AND DISCUSSION

3.3.1 Catalytic Activity and Crystallinity

The comonomer concentration in the feed greatly affects the properties of the synthesized copolymers. This effect is very prominent in terms of activity trends for the copolymer (See Figure 3-1). Increased activities of 18 %, 19 % and 15 % were recorded with just a single milliliter addition of comonomers 1-hexene, 1-octene and 1-decene respectively (See Table 3-1). A slight decrease in activity of DEC-4 compared to OCT-4 is due to the

steric hindrance caused by 1-decene (1-C₁₀) atoms [32]. Furthermore, higher amounts of comonomer added up the short chain branching (SCB) to the copolymers, and corresponds to lower DOC and T_m [33]. However, this effect is not that much prominent and approximately 1 K \pm 0.4 K decrease was noted in T_m for each milliliter comonomer addition. The comparative CRYSTAF profiles for the copolymers (See Figure 3-2) uphold the ¹³C NMR results, (See Table 3-1).

3.3.2 Thermal Analysis

The crystallization behavior of the copolymers was studied by DSC Q-1000 model equipment. The endotherms obtained for DEC-1 crystallization at different cooling rates (β) are shown in Figure 3-3a. The peak crystallization temperature (T_p) decreases with an increase in β , indicating that at lower cooling rates, the polymer chains have sufficient time to move from the melt phase to the crystal structure phase [14]. On the other hand, the high comonomer content in the feed decreases the crystallization onset and peak temperatures as shown in Figure 3-3b for different concentrations of 1-decene comonomer. The DEC-1 crystallizes earlier followed by DEC-2 and DEC-4, showing relatively less ethylene long chains in DEC-2 and DEC-4 because of the increase in the non-crystallizable fractions constituted by branched octyl- groups [See Table 3-1]. Figure 3-3c illustrates the comparative endotherms profiles for the comonomers HEX-1, OCT-1 and DEC-1, with the ^{13}C NMR analysis given in Table 3-1. The analysis of the results presented in Table 3-1 has shown that HEX-1 sample has the least comonomer incorporation and thus has the longest ethylene sequences compared to OCT-1 and DEC-1. The half-time for crystallization ($t_{1/2}$) increased with an increase in comonomer contents indicating that the high comonomer contents retarded the crystallization process (See Table 3-2).

3.3.3 Melt Crystallization

The crystallization kinetics of polymers can be explained by the well-known Avrami model which relates nucleation rate and lamellar crystal growth of the polymer as a function of crystallization time. The Avrami model is given by Equation (1).

$$X_t = 1 - \exp(-kt^n) \quad (1)$$

The term X_t represents the volume fraction of the polymer being transformed, n and k stands for the Avrami exponent and crystallization rate constant respectively. The parameter n is a function of nucleation process and it provides qualitative information about the nature of nucleation and growth process while k is the rate constant and it depends on the nucleation and crystal growth. For the non-isothermal crystallization kinetics study, direct use of Avrami model is not suitable since it holds good for the isothermal case and also excludes the secondary crystallization process. Thus for the non-isothermal process, a modified model in the growth rate constant is proposed by Jeizorny [16]. Further modification to the basic Avrami model is done by Ozawa [17] by considering that the crystallization process occurred in an infinite small isothermal steps at a constant cooling rate. The Ozawa model is given by the expression below:

$$X_t = 1 - \frac{\exp(-K(T))}{\beta^m} \quad (2)$$

$K(T)$ is the crystallization rate constant which is cooling rate dependent function, β is a cooling rate and m is the Ozawa exponent. Normally, Ozawa model is preferred over the conventional Jeizorny-Avrami model while operating at non-isothermal crystallization

conditions [34]. The relative crystallinity X_t can be calculated from the DSC exotherm.

The weight fraction α_t is calculated using the following expression:

$$\alpha_t = \frac{\Delta H(t)}{\Delta H_{total}} = \frac{\int_{T_o}^{T_i} \left(\frac{dH}{dt} \right) dt}{\int_{T_o}^{T_\infty} \left(\frac{dH}{dt} \right) dt} * 100 \quad (3)$$

Whereas, ΔH_{total} and $\Delta H(t)$ are the total heat released and heat released at a time t for the crystallization process respectively. The relation between weight fractions to volume fraction for the relative crystallinity is evaluated using the following formula:

$$X_t = \frac{\alpha_t}{\alpha_t + \frac{\rho_c}{\rho_a} [1 - \alpha_t]} \quad (4)$$

The crystalline phase and amorphous phase densities for the PEs are given by $\rho_c = 1.004$ and $\rho_a = 0.853$ respectively [19]. The melt crystallization was studied using DSC. The effect of comonomer type and the degree of branching were evaluated by using the Ozawa and Mo models.

Analysis by Ozawa Model

The Ozawa model given by equation (2) can be linearized to the following form

$$\ln[-\ln(1 - X_t)] = \ln[K(T)] - m \ln[\beta] \quad (5)$$

Equation 5 can be fitted to data obtained at different cooling rates. The data can be arranged in the form of $\ln(-\ln(1 - X_t))$ vs. $\ln(\beta)$ at different temperatures. The slope and intercept of the Ozawa-plots corresponds to m and $\ln(K(T))$ respectively. The Ozawa-plots can be easily generated for any selected temperatures (T_a) and plotting the

crystallinity at that temperature against the corresponding β . For the current study, four temperatures were used for the analysis. Since, the fraction of the total transformation of any copolymer is strictly a function of temperature, it is different from each copolymer at that specified temperature as shown in Figure 3-4, and therefore, undermining the comparison of different copolymers by Ozawa analysis albeit, the temperature is same. The temperatures for the analysis were selected in the close vicinity of the onset crystallization temperature for all the copolymers. The Ozawa-plots are shown in Figure 3-5, with the corresponding values of m and $K(T)$ listed in Table 3-3. For the Ozawa analysis, four cooling rates were used i.e. 1, 2, 3, and 5 K/min. as these heating rates provided better fitting. The suitability of the Ozawa model decreased with large variation in the cooling rates such as 1-30 K/min. This behavior can be due to the negligence of the secondary crystallization in the Ozawa theory, as the cooling rates are increased the crystallization peak is shifted towards a lower temperature. Therefore, when the difference in cooling rates is high, the phase of crystallization can be different for the copolymer at a specific temperature, which leads to the inapplicability of the Ozawa model [35]. For instance, let us consider HEX-1, at 1 K/min. and 380 K, the fraction of the total transformation is nearly 40%, while at 20 and 30 K/min., the fraction of the total transformation is nearly 23% and 11% respectively. Therefore, to avoid this issue, we have used only four cooling rates for the Ozawa analysis. Sajkiewicz et al. also reported that linear function by Ozawa model is obtained at lower cooling rates only, which was due to the fact that higher cooling rates, reduces the absolute crystallinity and an increase in the amorphous phase within the spherulites. Similarly, the crystallinity at which the spherulites impingement become dominant also increases with the cooling rate [36].

From the results listed in Table 3-3, it is evident that, for all the copolymers $K(T)$ decreases with an increase in temperature indicating a slower crystallization process at higher temperatures. The value of m was found close to 2, in the early stage of crystallization of all the copolymers indicating a 2 dimensional crystal growth. However, this value decreased rapidly with the decreasing temperature. The reason for this decrease can be the spherulites impingements which is dominant at low temperature. As stated earlier, the comparison of crystallization process for the different copolymers cannot be carried out through the Ozawa method. Therefore, for more quantitative analysis of the crystallization process, Mo-method should be evaluated.

Analysis by Mo Model

Mo method was first proposed by Liu et al. [18]. The Mo model equation can be derived by linearization and addition of Equation 1 and Equation 2.

$$nLn(t) + Ln(k_t) = Ln(K(T)) - mLn(\beta) \quad (6)$$

$$Ln[\beta] = Ln[F(T)] - \alpha Ln[t] \quad (7)$$

Equation (7) represents the straight line, with slope $\alpha = n/m$ and intercept

$$F(T) = \left[\frac{K(T)}{k_t} \right]^{1/m} \quad \alpha \text{ is the ratio of Avrami and Ozawa exponent. The parameter } F(T)$$

represents the degree of super cooling required to obtain a specific degree of crystallinity in unit time which simply indicates the degree of difficulty found in the crystallization process [18]. Mo plots can be generated by plotting $Ln(\beta)$ vs. $Ln(t)$ for any selected value of the fraction of total transformation. These relative crystallinities are used in calculating the time required to achieve that particular relative crystallinity at different cooling rates β . The calculated values for time thus obtained i.e. $Ln(t)$ is then plotted against $Ln(\beta)$. To successfully describe the crystallization process, Mo plots must be linear and straight line for a specific value of crystallinity [14]. For the current study, the Mo plots for all the samples were generated by selecting the relative crystallinities value of 0.2 to 0.8 with a step size of 0.2, which are shown in Figure 3-6 and the corresponding values obtained from model are listed in Table 3-4. The Mo plots are perfectly aligned and straight for all the copolymers samples which indicate that Mo method can suitably describe the crystallization process. From the analysis of the results in Table 3-4, it can be seen that $F(T)$ value increased more with the comonomer addition (degree of branching) as

compared to comonomer type, which reveals that the crystallization is more affected by the degree of branching rather than comonomer type. The value of α is almost constant indicating that Mo method is suitably describing the crystallization process.

3.3.4 ACTIVATION ENERGY

Activation energy (E_A) is the amount of energy that is released during the propagation of the crystalline chains within the polymer matrix during the phase transition. Kissinger method can be used for the calculation of E_A for LLDPE [19], which includes T_p and β [25]. E_A is calculated using the following expression:

$$\frac{d\left(\ln\left(\frac{\beta}{T_p^2}\right)\right)}{d\left(\frac{1}{T_p}\right)} = -\frac{E_A}{R} \quad (8)$$

Where, R is the universal gas constant. The values E_A can be evaluated from the slopes of

$\ln\left(\frac{\beta}{T_p^2}\right)$ vs. $\frac{1}{T_p}$ (See Figure 3-7) for the as-synthesized copolymers. Whereas, the

negative sign is representing that the crystallization process is exothermic in nature. Thus the lower values of E_A corresponds to easier crystallization process [19]. It is found that, for higher comonomer composition in the feed increases E_A , thus indicating a difficult crystallization process, (See Table 3-5). The E_A for the comonomers follows the order as HEX-1<OCT-1<DEC-1.

Figure 3-7. Kissinger plots for ethylene copolymers

Table 3-5. Summarized activation energies (E_A) obtained from Kissinger-plots

Sample No.	HEX-1	HEX-2	OCT-1	OCT-2	OCT-4	DEC-1	DEC-2	DEC-4
(E_A) kJ/mol	-940.1	-840.4	-856.8	-797.3	-677.8	-789.6	-681.1	-623.6

3.4 CRYSTAL THICKNESS DISTRIBUTION

The copolymers synthesized from polymerization of ethylene-1-alkene are semi crystalline in nature. The DOC of the copolymers decreases with addition of comonomers (See Table 1). The melting temperatures (T_m) at each point can thus be related to the equivalent dimensions of that crystal lamella (crystallite) by using Flory and GT equations also termed as MGT equation, given by Equation 9 [21,37,38].

$$T_m = T_m^o \left(1 - \frac{2\sigma_{ssfe}}{\Delta H_f^o L_{fclamella}} \right) \quad (9)$$

Where, T_m^o (equilibrium melting temperature of perfect crystal of ethylene homopolymer) = 418.65K; ΔH_f^o (heat of fusion per unit volume for the perfect crystal) = 290 J cm⁻³; $L_{fclamella}$ is the folded crystal lamellar thickness and σ_{ssfe} (crystallite specific surface free energy) = 90 mJm⁻² [24,39]. However, for the T_m^o for the copolymer ($T_{m,copolym}^o$) Equation 10 is used [22,23,39]. The main flaw in using MGT to calculate copolymer lamellar thickness distributions arise from the exclusion of branches from the copolymer crystals. The comonomer composition in the melt around the crystals changes during melting, hence, using the same $T_{m,copolym}^o$ to calculate L values along the whole melting curve, which might cause some error [38,40].

$$\frac{1}{T_{m,copolym}^o} = \frac{1}{T_m^o} + \frac{R}{\Delta H_u} (\ln X_A) \quad (10)$$

Where, ΔH_u is the heat of fusion of ethylene repeat unit and X_A is the mole fraction of ethylene in copolymer.

The LTD for various copolymers is shown in the Figure 3-8, and the WALT is summarized in Table 3-1. The MGT equation was implemented for studying the comonomer induced structural/enchainment defects in the copolymers. The LTD profile shrinks and narrows upon the further addition of comonomer, shows less crystallite in the polymer lattice due to high SCB. Therefore the additional branching effect acted as to break the relatively longer lamellae, resulting in an overall decrease in the width of the distribution [41]. This conforms to the positive effect of DOC on the WALT i.e. higher WALT is recorded for higher crystalline polymer and vice versa (See Table 3-1).

Figure 3-8. Lamellar thickness distribution (LTD) for: (a) 1-hexene; (b) 1-octene; (c) 1-decene; comonomers.

3.5 CONCLUSION

Ethylene-co- α -olefin polymerization was carried out using zirconocene complex with varying comonomer compositions. The comonomers (α -olefins) considerably influenced the melt crystallization and lamellar thickness distribution (LTD) of the copolymers. Mo method was found suitable for the copolymers melt crystallization, under study. The weight average lamellar thickness was found to decrease with comonomer addition. For the current study, Kissinger's activation energy (E_A) indicates that the crystallization process is more affected by the degree of branching rather than the comonomer type.

3.6 NOMENCLATURE

Table 3-6. Nomenclature

Symbols	Meaning (Units)
T_m	Peak melting temperature (K)
T_p	Peak crystallization temperature (K)
E_A	Activation energy (kJ/mol)
$t_{1/2}$	Half time for crystallization (min)
n	Avrami exponent
$K(T)$	Crystallization rate constant at any given temperature
m	Ozawa exponent
ΔH_{total}	Total heat released
$\Delta H(t)$	heat released at a time t
$F(T)$	Mo parameter also called degree of super cooling
α	Mo parameter (Ratio of Avrami and Ozawa exponent n and m respectively)
β	Cooling rate (K/min)
α_t	Weight fraction crystallized from melt
ρ_c	Crystalline phase density (kg/m ³)

ρ_a	Amorphous phase density (kg/m ³)
----------	--

ABSTRACT

In this research work, a zirconocene/MAO complex was used as a catalyst for the copolymerization of 1-hexene and ethylene in the presence of nano titania doped with 1% of manganese (TiO_2/Mn), which was used as a drop in filler. It was investigated from the ^{13}C NMR analysis that 1-hexene incorporation increases with the addition of nano filler. The degree of crystallinity (DOC), catalytic activity and molecular weight of the nanocomposites were studied by a differential scanning calorimeter (DSC), yield analysis and gel permeation chromatography (GPC) respectively. It was found that DOC, catalytic activity, molecular weight and molecular weight distribution were strongly influenced by the addition of nano filler due to the increase of 1-hexene incorporation. As a result, an increase in catalytic activity and a decrease in DOC were observed due to the addition of nano filler. The non-isothermal crystallization kinetics of the produced copolymer was studied using a model proposed by Ozawa and Mo *et al.* It was observed that the crystal growth rate is slowed by the nano filler. The Activation energy (E_A) was determined by the Kissinger method, and it was found that E_A is increased incrementally with the loadings of the nano filler, confirming a slower crystallization process.

Keywords: polymer nanocomposites, crystallization kinetics, nano-titania, catalytic activity

4.1 INTRODUCTION

Polyethylene (PE) is a widely used polymer because of its low production cost and remarkable properties. A huge increase in the production trends of PE has been noted over the last few decades due to its high demand in global plastic consumption [1]. The discovery of the metallocene catalyst has opened a new era of ethylene polymerization as it gives precisely designed products [2–6]. Linear Low Density Polyethylene (LLDPE) is one of the most important emerging resins of PE [7, 8]. In order to enhance heat resistance properties and strength of the PE, various nano fillers are utilized either by melt blending or by in-situ polymerization [9, 10]. During the production of polymer nanocomposites the nano filler remains in a discontinuous phase in the entire polymer matrix thus enabling them to have better properties than the unmodified polymer. The thus produced nanocomposites have high stiffness and tensile strength [1, 11]. The nano fillers have a high degree of interfacial interaction (due to their nano size) which provides high surface area compared to conventional fillers [11]. Several nano fillers including SiO₂ [1, 12, 13], TiO₂ [9, 10, 14, 15], Sepiolite (Mg₄Si₆O₁₅(OH)₂) [16], Al₂O₃ [17] and ZrO₂ [18, 19] are widely studied in literature. Among these nano fillers TiO₂ is the most promising inorganic nano filler because of its versatile properties, such as unique optical properties, anti-static behavior (used as antibacterial agent), and interesting photo catalytic properties [9, 14].

The crystallization of polymers is an important phase transition process. In fact, the rate of crystallization and the degree of crystallinity are key factors in polymer processing [20]. The crystallization process can be isothermal or non-isothermal. Generally most industrial processing is non-isothermal, and because of this, non-isothermal

crystallization kinetics has practical significance [21]. Various nano fillers, which impart unique characteristics to polymers, also affect the crystallization process. For instance, it has been reported that carbon nanotubes (CNTs) act as nucleating agents in the crystallization of LLDPE. It is also observed during isothermal crystallization the presence of a small amount of CNTs alter the morphology of LLDPE [22]. Similarly, it has also been observed that Carbon Nano Fibers (CNF) alter the lamellar thickness and lamellar thickness distribution [23].

Many Models such as Jeizorny, Ozawa and Mo [24–27] were used to describe non-isothermal crystallization kinetics of all derivatives of PE (high density PE (HDPE), low density PE (LDPE), linear low density PE (LLDPE), and ultra-high molecular weight PE (UHMWPE)). In this study the Mo-Model is applied to the analysis of non-isothermal crystallization kinetics of LLDPE-TiO₂ nanocomposites.

4.2 EXPERIMENTAL METHODS

4.2.1 Chemicals

A Bis(cyclopentadienyl zirconium (IV) dichloride) > 98% (C₁₀H₁₀Cl₂Zr), Methylaluminoxane (MAO), nano titania doped with 1% manganese (TiO₂/Mn) (<100 nm) and all other chemicals were provided by Sigma Aldrich and were used as received.

4.2.2 *In-Situ* Polymerization Reaction

Ethylene/1-hexene copolymerization was carried out in a 250 mL round bottom flask (semi batch reactor) equipped with a magnetic stirrer. Inside the glove box the reactor was charged with 20 μmoles (6 mg) of a zirconocene catalyst and different dosages (5, 15 and 30 mg) of the nano filler and 80 ml of solvent (toluene). The airtight reactor was then

immersed in a constant temperature bath at 30 °C. Once the temperature of the bath and reactor reached equilibrium, the nitrogen was removed from the reactor using a vacuum pump. The ethylene gas at a pressure of 1.3 bar was fed to the reactor in order to start the polymerization process. After two minutes of saturation with ethylene, 1 mL of the comonomer (1-hexene) was introduced into the reactor. Five mL of cocatalyst (MAO) was added to reactor just after 3 minutes of saturation with the comonomer. The total reaction time was 30 minutes with a stirring speed of 600 rpm, after which the polymerization process was quenched by adding acidified methanol (5 vol. % HCl) followed by stirring for 45 minutes. The copolymer thus obtained from the copolymerization of ethylene/1-hexene was filtered and kept in an oven at 50 °C for 10 hours before weighing to calculate the activity. The abbreviations used in this section are E-H-0 (control), E-H-5, E-H-15 and E-H-30, where the numbers represent the amount of nano filler in milligrams.

4.2.3 Polymer Characterization

1. The thermal behavior of the copolymer was determined using a DSC-Q1000, instrument. The heating rate used in this study was 10 °C /min. The melting temperature (T_m) was obtained from the heating cycle while the crystallization temperature (T_c) was obtained from the different cooling cycles.
2. Crystallization analysis fractionation (CRYSTAF) (model 200 CRYSTAF instrument provided by Polymer ChAR) was employed for the analysis of the chemical composition distribution (CCD) of ethylene/1-hexene copolymer and its nanocomposites. The samples were dissolved in 1, 2, 4 trichloro-benzene (TCB) at 150

°C for 60 minutes and then allowed to cool at 0.1 °C /min. The infrared detector (dual wavelength) determined the polymer crystallize in the solution.

3. The carbon13 nuclear magnetic resonance (¹³C-NMR) technique was utilized to study the copolymer microstructure. The samples were prepared by dissolving 25 mg of polymer in TCB at 120 °C with a few drops of deuterated benzene. The comonomer mole fraction was determined by using the integration of peaks relative to the isolated methylene resonance on the spectroscopy (largest peak assigned at 30ppm on the x-axis scale) [28, 29].

4. The gel permeation chromatography (GPC) technique was used to find the molecular weight (M_w) of the polymer nanocomposites. Nearly 5 mg of the polymer was dissolved in 10 mL TCB at 160 °C for 3 hours in a 40 mL glass vial, sealed with a Teflon coated cap. The equipment was calibrated using polystyrene (PS) standards.

4.3 RESULTS AND DISCUSSION

4.3.1 Catalytic Activity

From the yield analysis, catalytic activity was calculated and is tabulated in Table 4-1. The catalytic activity increases with the increase in the nano filler amount and reaches its maximum value at 15 mg of the nano filler. Similar results were reported for HDPE with the same nano filler [10]. The high catalytic activity and lower molecular weight (M_w) was observed at the optimum dose of the nano filler. The increase in catalytic activity is reported due to the high surface area of the nano particles which provide better distribution of catalytically active centers throughout the particle as a result monomers get easy access to coordinate with each other [14]. The doped manganese (Mn) also plays a vital role for getting high catalytic activity because of having the intrinsic activity of the

active species itself (i.e. Mn) present on doped TiO₂ [30]. The cocatalyst MAO adsorbed on the surface of nano filler by physical interaction. The adsorption phenomenon lowers the intrinsic activity of the active species as well as the availability of MAO at high doses of filler addition. Furthermore the presence of a high amount of the filler (as compared to the catalyst) boosts the agglomeration process of filler around the catalyst. As a result, a relatively lower yield is obtained during the lateral stages i.e. 30 mg of filler addition. The phenomena is termed as steric hindrance [31, 32]. Figure 4-1 shows the error bars for the variance in activities and crystallinities for the repeated runs. The change in the molecular weights of the polymer nanocomposites due to filler addition is not significant.

Table 4-1. Experimental activity data and Characteristics for LLDPE-TiO₂/Mn nanocomposites ^a using zirconocene catalyst

4.3.2 Crystallinity of LLDPE- TiO₂/Mn Nanocomposites

The DOC and T_m are tabulated in Table 1 obtained from DSC results. The decreasing trend in the crystallinity is observed as a result of filler addition and reaches its minimum value at a filler dosage of 30 mg. CRYSTAF is utilized for finding the CCD for the synthesized nanocomposites as shown in Figure 4-2. The broadness in the peak increases across the increase in the filler addition along with a slight decrease in the peak temperature, which clearly indicates that there is the addition of more short chain branching to the polymer structure due to 1-hexene incorporation [33]. The DOC is highly influenced by 1-hexene incorporation [29, 34]. At 30 mg of the filler dosage, there is very prominent change in the peak temperature of the nanocomposites which is due to the high comonomer incorporation supported by ¹³C-NMR results obtained, tabulated in Table 4-2. The nano-TiO₂/Mn thus alters the structure of the polymer by attributing more 1-hexene incorporation and lowering the DOC. The minimum effect of nano-TiO₂/Mn on crystallinity could be related to the effect of TiO₂/Mn on the low crystalline active sites only. This is supported by the negligible change in peak temperature of the high crystalline fraction on the CRYSTAF curves.

Figure 4-2 CRYSTAF profiles for LLDPE-TiO₂/Mn nanocomposites

Mole % of 1-hexene (¹³ C NMR)	1.310	1.312	1.315	1.776

4.3.3 Melt Crystallization

The melt crystallization of polymer can be explained by the well-known Avrami model. The Avrami theory relates the nucleation rate and lamellar crystal growth to the volume fraction of transformed material and the crystallization time. Avrami model is given by Eq.1

$$X_t = 1 - e^{-kt^n} \quad (1)$$

X_t is the volume fraction of transformed material, n is the Avrami exponent and k is crystallization rate constant. n is a function of nucleation process while k is the growth function and it depends on the nucleation and crystal growth. n provides qualitative information about the nature of nucleation and growth process. Since the Avrami model deals with the isothermal crystallization process, it is not suitable to be applied directly in non-isothermal case. Likewise this model excludes the effect of growth site impingement and secondary crystallization process. For the analysis of non-isothermal process Jeizorny [26] proposed a modification in the growth rate constant. Similarly, Ozawa [27] extended the Avrami theory for prediction of non-isothermal process. The Ozawa model is based on the assumption that the crystallization process occurs in infinitesimally small isothermal steps at a constant cooling rate. The Ozawa model is given by Eq.2 as followed.

$$X_t = 1 - \frac{\exp(-K(T))}{\beta^m} \quad (2)$$

Where $K(T)$ is a function of the cooling rate β and the Ozawa exponent m . It is reported that as compared to Jeizorny-Avrami model, the Ozawa model works well in case of non-

isothermal crystallization [35]. The relative crystallinity X_t can be calculated from the DSC exotherm. First the weight fraction α_t is obtained by the following relation.

$$\alpha_t = \frac{\Delta H(t)}{\Delta H_{total}} = \frac{\int_{T_o}^{T_i} \left(\frac{dH}{dt}\right) dt}{\int_{T_o}^{T_{\infty}} \left(\frac{dH}{dt}\right) dt} * 100 \quad (3)$$

Where $\Delta H(t)$ is the heat released at time t while ΔH_{total} is the total heat released during the crystallization process. The weight fraction can be transformed to volume fraction by the formula given below

$$X_t = \frac{\alpha_t}{\alpha_t + \frac{\rho_c}{\rho_a[1 - \alpha_t]}} \quad (4)$$

Where, ρ_c and ρ_a are the densities of crystalline and amorphous phases respectively. The values of ρ_c and ρ_a are 1.004 and 0.853 for PE [36].

Analysis by Ozawa model

The Ozawa model can be applied to the non-isothermal crystallization process, carried out at different cooling rates. Eq.5 can be simplified by linearization as shown below.

$$\ln[-\ln[1 - X_t]] = \ln[K(T)] - m\ln[\beta] \quad (5)$$

The parameters of the model i.e. m and $K(T)$ can be obtained from the slope and intercept of plot of $\ln[-\ln[1 - X_t]]$ vs. $\ln[\beta]$. The Ozawa model plots can be generated by considering a temperature and then plotting the relative crystallinity at that temperature to the corresponding cooling rate. The temperatures selected here are, 365, 368, 371, 374,

377 and 380 K. The Ozawa plots are shown in Figure 4-3 (a-d) and the results are listed in Table 4-3.

Analysis by Mo-model

The crystallization kinetics model proposed by Liu *et al.* [24] is derived from the Jeizorny-Avrami equation given by Eq. 1 and the Ozawa equation given by Eq.2 [25, 38].

After linearization and addition of Eq.1 & 2, the equation becomes

$$n \ln(t) + \ln(k_t) = \ln(K(T)) - m \ln(\beta) \quad (6)$$

Upon simplification, the above equation is reduced to

$$\ln[\beta] = \ln[F(T)] - \alpha \ln[t] \quad (7)$$

Whereas, $F(T) = \left[\frac{K(T)}{k_t} \right]^{1/m}$ and $\alpha = n/m$ i.e. the ratio of the Avrami exponent to the Ozawa exponent. $F(T)$ represents the degree of super cooling required to obtain a specific degree of crystallinity in unit time. A higher $F(T)$ refers to a comparably difficult crystallization process and vice versa [24]. According to Eq.7 for Mo-model to successfully describe the crystallization process, plots of $\ln[\beta]$ against $\ln[t]$ should be linear. The Mo-model plots can be generated by considering a percent relative crystallinity and then calculate the time required to achieve that crystallinity at different cooling rates. The corresponding values of $\ln(t)$ can then be plotted against $\ln[\beta]$. For the present case similar Mo-model plots were generate according to Eq.4. The plots are presented in Figure 4-4 (a-d) and the summarized results are listed in Table 4-4. The linearity of the plots shows that this model is valid for the LLDPE and LLDPE-TiO₂/Mn nanocomposites. $F(T)$ and α were obtained from the intercept and slope of lines in Figure 4 respectively. As stated above that $F(T)$ refers to the degree of super cooling required for a unit degree of crystallinity, it can be observed from the results in Table 4-4, that as the relative crystallinity increases the $F(T)$ increases as well, which indicates that at higher

relative crystallinity more super cooling is required to crystallize the polymer melt. Similarly, it can also be observed that at a specific value of X_t , the $F(T)$ for LLDPE-TiO₂/Mn nanocomposites is high as compared to neat LLDPE. This means the crystal growth process is slower for LLDPE-TiO₂/Mn nanocomposites. This conclusion is consistent with the Ozawa analysis.

4.3.4 Activation energy (EA)

E_A is related to the energy required for transporting the crystalline chains of polymer through the phase [39]. One approach to determine this energy is by taking into account the variation in peak temperature for crystallization (T_p) with the cooling rate, according to the following relationship [40].

$$\frac{d(\ln(\frac{\beta}{T_p^2}))}{d(\frac{1}{T_p})} = -\frac{E_A}{R} \quad (8)$$

Where, R is the universal gas constant. E_A can be evaluated from the slope of $\ln(\frac{\beta}{T_p^2})$ vs. $\frac{1}{T_p}$ shown in Figure 4-5. E_A turned out to be -603.86, -589.32, -559.35 and -556.53 kJ/mol, for E-H-0, E-H-5, E-H-15 and E-H-30 respectively. Since the crystallization process is exothermic i.e. transformation from melt to crystalline form, so the greater magnitude of absolute E_A favors the process [36, 41]. For the present case it is found that with the addition of nano-TiO₂/Mn, E_A is increased, indicating a difficulty in the crystallization process. This phenomenon can be attributed to adsorption of polymer segments by the nano filler, which then prevents the movement of molecular segments and thus makes the crystallization difficult. Similar observations were also made in the case of HDPE/nano-SiO₂ nanocomposites [42].

The current study only considers the laboratory work and is aimed to obtain a better idea about the role of nano-TiO₂/Mn upon the activity of the metallocene catalyst,

microstructural behavior of the copolymer and non-isothermal crystallization kinetics. It is necessary at this stage to evaluate other physical properties, including mechanical properties and calorimetric properties.

Figure 4-5. Kissinger Plots for LLDPE and LLDPE-TiO₂/Mn nanocomposites

4.4 CONCLUSION

Nano-TiO₂/Mn significantly influences the catalytic activity as well as the percentage crystallinity but it has very minimal effect on T_m . The optimum dose is found to be 15 mg of the nano filler to give the maximum catalytic activity. The drop in nano-TiO₂/Mn alters the polymer structure by adding more short chain branching to its backbone, thus decreasing the DOC. 1-hexene incorporation is determined by ¹³C NMR which clearly indicates that, 1-hexene incorporation is increased by filler addition. The Ozawa-method and Mo-method successfully described the non-isothermal crystallization of LLDPE and LLDPE-TiO₂/Mn nanocomposites. E_A was calculated from Kissinger method. It was found that the crystallization process is retracted by presence of the nano filler due to steric hindrance, as indicated by an increase of cooling function and E_A , and decrease in the crystallization rate constant.

Abstract

Hybrids of graphene (G) and layered double hydroxides (LDHs) are promising nanomaterials due to their versatile properties and the large number of composition/preparation variables available for fine-tuning. Several techniques are available for the synthesis of these novel G/LDHs nanocomposites. This article reviews the recent developments in their synthesis and applications in the oxygen evolution reaction, supercapacitors, hybrid sensors, adsorption, catalysis, water purification, and flame retardant materials.

5.1 Introduction

Graphene (G) and chemically modified graphene such as graphene oxide (GO) have special and much desired characteristics due to their unique electrical, mechanical, thermal, and surface properties [1–3]. Layered double hydroxides (LDHs) are inorganic materials with a 2D highly tunable brucite-like layered crystal structure. These inorganic clays contain layers of positively charged metal hydroxides with multivalent anions for neutrality. The LDHs are generally represented by formula $[M^{2+}_{(1-x)}M^{3+}_x(OH)_2]^{x+}(A^{n-})_{x/n} \cdot mH_2O$. Where, M^{2+} and M^{3+} represents the di and trivalent metallic cations (M^{2+} can be Mg^{2+} , Ni^{2+} , Co^{2+} , Zn^{2+} *etc.* whereas M^{3+} can be Al^{3+} , Fe^{3+} *etc.*) and A^{n-} is an anion such as OH^- , F^- , NO_3^- , Cl^- , CO_3^{2-} or SO_4^{2-} . The water molecules embedded between the lamellar structures are initiating the synthesis process. Typically, x varies in the range 0.22 to 0.33 [4,5]. The LDHs can be used in a variety of potential applications due to their low cost, facile synthesis, thermal stability, and chemical versatility [6].

Hybrid nanomaterials developed using LDHs and carbon based materials such as carbon nanotubes (CNTs), carbon nanofibers, and graphene has invoked a great deal of interest lately because they have unique properties due to the combination of the special properties of the parent materials. Of particular interest is graphene sandwiched between two cationic layers of LDHs to yield a new material with improved properties as compared to the pristine graphene [7,8]. The layered structure of LDHs not only prevents the restacking of graphene but also improves the catalytic activity and thermal stability of the composite [9]. The general schematic of a sandwich assembly is shown in Figure 5-1.

The novel G/LDHs nanocomposites can be used in a variety of applications such as supercapacitors [11–13], as magnets [14,15], catalysis [10,16], electrochemistry [17], as nanofillers for polymer nanocomposites [18–20], in water treatment [21,22], in medical applications [23–25] and in many other areas.

A few review articles that focus on the synthesis and applications of individual LDHs, graphene nanocomposites, and carbon/LDHs are available [26–30]. Zhao et al. reviewed the research progress and new developments in the area of hierarchical nanocomposites derived from nanocarbon and LDHs [30]. Shao et al. highlighted the progress in the design, synthesis and characterization of LDHs for applications in electrochemical energy storage and conversion [29]. In this paper, the methods used for the synthesis of G/LDHs nanocomposites and their novel and potential applications in the areas of oxygen evolution reaction, supercapacitors, catalysis, sensors and polymer nanocomposites are reviewed. To the best of our knowledge, this is the first review dealing with the latest developments in the field of G/LDHs nanocomposites.

5.2 SYNTHESIS OF G/LDHs NANOCOMPOSITES

5.2.1 Co-precipitation synthesis

The co-precipitation method is a method that is used extensively for the synthesis of a variety of LDHs and their novel carbon based hybrids such as CNT/LDHs and G/LDHs [31–33]. A schematic of the formation of a hybrid is shown in Figure 5-2. Initially, graphene nanosheets (GNS) or GO are ultrasonicated in deionized water (DI) and are mixed with a solution of the precursor salts (M^{2+} : M^{3+}) prepared under vigorous stirring at a controlled pH. Reducing agents are primarily used to adjust the pH and reduce GO to reduced graphene oxide (rGO) or GNS [23]. Commonly used reducing agents include urea, hydrazine, glucose, and sodium sulfide. Though, glucose is preferred over hydrazine because it is less toxic and environmental friendly [34]. The suspension is then allowed to reflux for 24-48 h at 90 ± 10 °C with continuous magnetic stirring followed by centrifuging and washing with DI water and pure ethanol to remove any impurities. The G/LDHs nanocomposites thus obtained are dried for 48 h at 60 °C. In this method, the charge densities of matrix cations within the hydroxide layers are maintained. The pH must be controlled in order to precipitate both M^{2+}/M^{3+} cations simultaneously to prevent $M(OH)_2$ remaining as an impurity [35]. However, a wide range of crystallite sizes are obtained due to the complex aging process [36]. Several G/LDHs nanocomposites along with their synthesis parameters are tabulated in Table 5-1.

5.2.2 One-pot hydrothermal synthesis

Hydrothermal synthesis method, also known as the urea-hydrolyzed method, is also used for the synthesis of G/LDHs nanocomposites. This technique involves the mixing of urea with a solution of precursor salts, followed by the addition of an ultrasonicated suspension of GO. The resultant mixture is then transferred to a Teflon-lined stainless steel jacketed autoclave reactor and heated at a desired temperature for an extended period to allow reduction of GO. Although, Although, LDHs and their GO or rGO hybrids with a uniform crystallite size and shape have been successfully synthesized using the urea-hydrolyzed method, the resultant product is typically contaminated with carbonate ions. Moreover, this method is of limited application in some cases, especially for preparing Cu^{+2} and Cr^{3+} cationic LDHs [40]. Hexamethylenetetramine (HMT) has been used instead of urea for selected applications. The high temperature of the hydrothermal process favors the formation of ammonia from HMT, making the aqueous solution more alkaline [41]. The advantage of hydrothermal synthesis over coprecipitation is that it yields a well crystallized nanocomposite with uniform morphology [7,42]. These rGO/LDHs nanocomposites with a uniform crystallite size and morphology have displayed superior properties over pristine LDHs in the field of supercapacitors. However, using a large amount of rGO tends to decrease the crystallinity of the nanocomposites [43]. A schematic illustration of a typical hydrothermal one-pot synthesis is shown in Figure 5-3. Experimental conditions that have been used for one-pot synthesis are summarized in Table 5-2. There is a need to develop a continuous flow process, which is rapidly gaining the interest and attention of researchers [44].

5.2.3 Exfoliation-restacking synthesis

This method involves the delamination of LDHs (intercalated with nitrates or chlorides) and the subsequent attachment of these exfoliated LDHs through self-assembly to the surface of GO due to electrostatic interactions [9]. The presence of functional groups attached to GO makes their colloidal solutions strongly negative, while LDHs, which are positively charged metallic hydroxides with replaceable anions, can form positively charged species through exfoliation. Thus, exfoliation and restacking is a good route to obtain nanocomposites of GO/LDHs or chemically modified G/LDHs [11]. These exfoliated 2D LDHs provide nucleation sites for the growth of graphene. Homogenous anchoring of GNS and uniform crystal growth are key factors for the successful application of these nanocomposites [53]. However, exfoliation of LDHs is difficult due to the strong electrostatic forces between the metallic hydroxides and intercalated anionic layers. These forces can be weakened by introducing solvents such as formamide [11,54], water [55], and sodium dodecyl sulfate (SDS) [56]. Typically, the LDHs are ultrasonicated in formamide solution initially and then added to an ultrasonicated GO suspension for the restacking process. The resultant mixture is stirred at least for 12 h and then centrifuged and washed. Washing 4-5 times with DI water followed by washing with pure ethanol is required to remove all the impurities. The resulting solid is then dried in a vacuum oven at 80 °C overnight [54]. The nanocomposites obtained through this process possess high phase purity and relatively high crystallinity [41]. A schematic illustration of the formation of the hybrid G/NiAl complex through exfoliation-restacking is presented in Figure 5-4. Table 5-3 summarizes the exfoliation-restacking methods reported in the literature and the conditions used in them.

5.2.4 Characterization of DSSCs

G/LDHs nanocomposites can be formed by layer-by-layer (LBL) assembly using the electrostatic attractions between the negatively charged GO and positively charged materials [53]. Polymeric solutions such as poly(diallyldimethylammonium chloride) (PDDA), polyaniline (PANI), poly (ethylene imine) (PEI) and poly (vinyl alcohol) (PVA) etc. can be used to obtain a cationic surface required for LBL assembly. The product exhibits a highly tunable hybrid architecture with nanoscale precision, uniform particle size, and a film morphology. [60,61]. Furthermore, a variety of substrate supports can be used for the deposition of negatively charged GO and positively charged LDHs. Dong et al. formed multilayered composites containing CoAl LDHs and GO by LBL assembly using a PDDA-coated indium tin oxide (ITO) substrate. The CoAl LDHs were synthesized using the co-precipitation method followed by exfoliation using formamide solution. The exfoliated GO, obtained via the modified Hummer's method, is ultrasonicated to obtain a uniform dispersion. The coated substrate was then immersed in the GO dispersion followed by immersion in the exfoliated LDHs dispersion. After each immersion, the coated substrate was washed and dried with nitrogen to remove impurities and un-exfoliated components. The process was repeated several times to achieve the desired number of layers [61]. A similar procedure, schematically depicted in Figure 5-5, was also adopted by Chen et al. for the formation of the CoAl/GO/PVA hybrid by LBL assembly. The CoAl-LDHs, obtained from the hydrothermal treatment of precursor salts, were exfoliated using formamide solution. The quartz glass sheets (substrate) were thoroughly washed with DI water and dried in a nitrogen stream. The cleaned glass substrate was coated with hybrid films by repeated cyclic immersion for 10 minutes each

in the three media to obtain the desired number of layers. After each immersion step the coated substrate was washed and dried with nitrogen. These immersion steps included the following: (a) dipping of the substrate in the exfoliated CoAl-LDHs suspension; (b) dipping of the substrate in the aqueous PVA solution (1 wt. %); and (c) dipping in the ultrasonicated GO suspension. The thin films thus formed contained GO, which was further reduced to films of CoAl/G/PVA nanocomposites by immersing the coated substrate in hydrazine/N,N-dimethylformamide (0.5/30 vol. ratio) solution [20].

Figure 5-5. Schematic representation of the layer-by-layer assembly procedure [20] with permission from ACS

5.2.5 In-situ synthesis

The *in-situ* synthesis, also referred as surface synthesis, typically involves two steps. Initially, the boehmite (AlOOH) primer solution is obtained by hydrolyzing aluminum isopropoxide, followed by LBL assembly of the AlOOH gel on GO [12,62]. The precursor, denoted by GO/AlOOH, is known as the base or substrate. The AlOOH gel helps reduce surface roughness and enhances the adhesion properties. Typically, cobalt or nickel based asymmetric 3D nanocomposites are formed by this technique. The activated surface provides Al sites which are utilized as the source of the trivalent cations[62]. The GO/AlOOH solution is typically formed by adding 20 mL of the AlOOH solution to 6 mL of an ultrasonicated GO suspension followed by vigorous mixing for 12 h. Solid is separated by centrifugation, washed with ethanol several times to remove impurities and dried at room temperature. The dried GO/AlOOH sheets are then dispersed in DI water and ultrasonicated for 0.5-1 h. The suspension is then transferred to an autoclave along with the precursor salt solution of 0.5 molar $\text{Ni}(\text{NO}_3)_2$ and 0.3 g urea for hydrothermal reaction. Finally, the resultant product is centrifuged and washed with DI water and ethanol to remove any traces of impurities and subsequently oven dried for 48 h at 80 °C [12,21]. *In-situ* growth process has been used to fabricate a hierarchical 3D nanocomposite, in which arrays of LDHs are grown on both sides of the substrate [12]. The uniform size and morphology of the nanocomposites are attributed to the *in-situ* growth of the arrays of LDHs on the surface of graphene sheets during the hydrothermal process [12,41,62]. The schematic illustration of the LBL process is shown in Figure 5-6 and a summary of methods used is listed in Table 5-4.

5.2.6 Others

Solvothermal technique is a modified form of the urea-hydrolyzed method in which DI water is replaced with other non-aqueous solvents. The precursor salts are first dissolved in a non-aqueous solvent followed by addition of an ultrasonicated GO suspension. The final step involves treatment in an autoclave reactor. The remaining steps and the operating parameters are similar to those of urea-hydrolyzed synthesis [13,64]. Microwave technology can be used as an alternate for the traditional hydrothermal synthesis using an autoclave for the rapid synthesis of G/LDHs nanocomposite shown schematically in Figure 5-7 [8]. Recent studies describe the use of potentiostatic deposition of LDHs on the rGO electrode to form G/LDHs nanocomposites with a unique 3D morphology [65]. Other methods used for the synthesis of G/LDHs nanocomposites are listed in Table 5-5.

5.3 Results and Discussion

Currently, G/LDHs nanocomposites are of increased scientific interest. These materials are being tested for their applications in catalysis, oxygen evolution reaction (OER), supercapacitors, flame retardant materials, nanofillers, photo-catalysts, and sorbents. This section highlights the performance of various G/LDHs nanocomposites used in different applications.

5.3.1 Oxygen evolution reaction

The oxygen evolution reaction plays an important role in sustainable energy systems such as fuel cells, solar cells and metal-air batteries [67]. Molecular oxygen is generated in the OER, which is highly influenced by the sluggish kinetics due to the high overpotential [34]. Thus, cost-effective and efficient electrocatalysts are critically important as they reduce the large overpotential and accelerate the reaction. Although metal oxides such as IrO₂ and RuO₂ are very active and durable electrocatalysts for OER, however, the high cost and scarcity considerably limit their applications [68,69]. Transition metal oxides are a viable alternative due to their abundance and high stability [70–73]. A range of carbon materials such as CNTs, graphene, carbon quantum dots and nitrogen doped graphite have been recently identified as good OER catalysts with a multifunctional framework [74–76]. Due to the electrostatic interactions between two oppositely charged nanosheets LDHs can act as effective electrocatalysts. Introducing graphene into monolayers of LDHs enhances their OER performance in three ways. First, graphene provides a large surface area, thereby increasing the available number of active sites. Secondly, graphene provides electrically conductive pathways for the LDHs and control the aggregation of LDHs crystals. Thirdly, the electrostatic interactions between the positively charged

LDHs and negative charged GO at molecular scale provides direct contact between the transition metal and carbon, thus shortening the diffusion distance [56,67,77].

The onset overpotential (η_{onset}), the overpotential required to reach a current density of 10 mA cm^{-2} (η_{10}) and the Tafel slope are important parameters which determine whether OER can be used in a water splitting device [67]. The OER data for different G/LDHs nanocomposites are given in Table 5-6. Among them, NiFe LDHs are the most promising catalysts for future OER systems [78]. The hybrid formed by the combination of NiFe LDHs with GO was recently reported as a potential electrocatalyst for OER. The synergy between the catalytic activity of NiFe LDHs and the electrical conductivity of graphene makes these nanocomposites excellent electrocatalysts for OER [58,79]. A G/NiFe LDHs nanocomposite possessing an overpotential of 0.195V and a turnover frequency at overpotential of 0.98 s⁻¹ was synthesized by Long et al. to overcome the limitations of specific surface area and conductivity [80]. Wang et al. reported that nanocomposite of G/NiFe LDHs possess a remarkably low overpotential of 324 mV at 10 mA cm^{-2} [67]. Youn et al. synthesized GO/NiFe LDHs nanocomposites using the solvothermal method. GO/NiFe LDHs nanocomposites showed superior properties compared to NiFe and IrO₂. The GO/NiFe LDHs nanocomposites possesses a lower value of η_{10} (245 v) which is much lower than that of bare NiFe [77]. Ma et al. studied the effect of the Ni and Fe content on the properties of GO/NiFe LDHs nanocomposites and showed that the performance improved with increasing Fe content. An overpotential as low as 210 mV was achieved for GO/NiFe LDHs nanocomposites [58]. Xia et al. used a three-step process to form GO/NiFe LDHs nanocomposites. The resulting nanocomposite exhibited excellent OER activity [81]. Zhu et al. introduced a mildly oxidized graphene/ CNT

hybrid to improve the properties of NiFe LDHs [82]. The resulting material contains a porous structure with a more hydrophilic surface, which enhances the smooth permeation of electrolytes. The nanocomposite also exhibited superior OER performance with an η -onset of 240 mV. Most of the scientific work in OER applications is limited to G/NiFe LDHs nanocomposites. Other G/LDHs nanocomposites have to be investigated for their potential use in OER applications.

Table 5-6. OER data for different LDHs nanocomposites

Nanocomposites	$\eta_{\text{onset}}^{\text{a}}$ (mV)	η_{10}^{b} (mV)	Tafel slope (mV decade ⁻¹)	Ref

5.3.2 Supercapacitors

Supercapacitors are high-capacity energy devices that have attracted attention due to their high power density, energy density, low maintenance cost, and long life cycle [83–85]. Super capacitors are divided into two main categories of redox electrochemical capacitors and electric double layer capacitors. Due to the presence of both double-layered capacitance and Faradaic pseudo-capacitance simultaneously, LDHs are thus attractive materials that can be used as supercapacitors. However, the performance is affected by their low electrical conductivity. A specific capacitance of 552 F g^{-1} at a current density of 1 A g^{-1} with a lower specific capacitance retention rate of 31.9 % at 8 A g^{-1} have been recorded for pure CoAl LDHs [59]. Owing to the ease of chemical modification, graphene can be coupled with a various LDHs and the resulting nanocomposites have great potential for supercapacitor applications [1,3]. Graphene can be used to overcome the poor high-rate charge and discharge capability resulting from the low electrical conductivity. The addition of graphene into LDHs provides a large surface area, high electrical conductivity, mechanical flexibility, and thermal/chemical stability [11,12]. Thus, due to the synergetic effects the hybrid material containing LDHs and graphene has better capacitance with a notable improvement in the capacitance retention rate at higher current densities than the parent materials [11,13,39,59,85–89]. Other than graphene activated carbon, porous carbon, CNTs, carbon onions, and nanohorns are also used in electric double layer capacitors [3,9,90,91]. The energy storage capability of supercapacitors is still low compared to ion batteries, and efforts are underway to improve the energy density [54].

Huang et al. evaluated the electrochemical properties of GO/CoAl LDHs nanocomposites and obtained a specific capacitance of 1296 F g^{-1} at a current density of 1 A g^{-1} . In addition, 90.5% of the initial capacitance was retained at a high current density (15 A g^{-1}) after 1000 cycles [11]. Wang et al. synthesized hybrid GO/CoAl LDHs nanocomposites with a specific capacitance of 1031 F g^{-1} at 1 A g^{-1} [54], indicating that the GO/CoAl LDHs nanocomposites are well suited to be used as supercapacitor electrodes. Xu et al. synthesized and used 3D G/NiAl LDHs nanocomposites as a supercapacitor electrode with a specific capacitance of 1329 F g^{-1} at a current density of 3.57 A g^{-1} . After 500 cycles at 15.30 A g^{-1} , the specific capacitance was remained at 91% of the initial value. However, a similar treatment of pure NiAl LDHs resulted in a retained specific capacitance of 74 % [12]. Yang et al. developed ternary nanocomposites containing GO/CNT/NiAl LDHs which possess a 3D structure with enhanced supercapacitor capabilities [64]. The specific capacitance and the current density of some G/LDHs are listed and compared with the parent LDHs in Table 5-7.

Table 5-7. Summary of specific capacitances and cyclic performance of G/ LDHs nanocomposites

Nanocomposite	Amount of GO used	Specific capacitance (F g ⁻¹)	Current density (A g ⁻¹)	No. of cycles	Current density (A g ⁻¹)	Specific capacitance retained %	Ref

5.3.3 Catalysts and sorbents

The high interlayer spacing, high surface area, positive charge on the surface, high anion exchange capacity, and the high number of active sites allow LDHs to be used as anion exchangers, catalysts, and adsorbents [4–6,26,27]. The adsorption capacity of LDHs can be enhanced by decreasing the particle size, by techniques such as delamination [97]. As they can easily pile up and restack [6,9] due to the strong surface charge density between the LDHs monolayers, it is difficult to keep the LDHs in an orderly and uniform manner. The restacking can be minimized by introducing negatively charged GO into the layers of LDHs which provide the required support and stability to the LDHs sheets [9,57]. The nanocomposites of GO or rGO supported LDHs can thus be used for the adsorption of CO₂ [57], removal of heavy metals from water [22], and photo-catalysis [55]. Forming graphene nanocomposites with pure LDHs exponentially increases its adsorption capabilities. Garcia-Gallastegui et al. showed that the adsorption capacity of MgAl LDHs increased by 62 % with the addition of only 7 wt. % of GO [10]. Wang and co-workers showed that the CO₂ adsorption significantly improved with the incorporation of 6.54 wt. % of GO in a MgAl LDHs as compared to the pure material [57]. G/LDHs nanocomposites have been used for the removal of heavy metals such as uranium (U(VI)) [21], chromium (Cr(VI)) [22], arsenic (As(V)) [48], Cd²⁺ [98], lead (Pb(II)) and 2, 4 dichlorophenoxyacetic acid [49] from water. Tan et al. studied the removal of uranium (VI) from water using the rGO/NiAl LDHs nanocomposites [21]. As this nanocomposite has a large surface area and mesoporous characteristics, it shows enhanced adsorption of contaminants from aqueous media. The nanohybrid adsorbent can also be regenerated [21]. In another similar study hexa-valent chromium was successfully removed from

wastewater using the G/MgAl LDHs. The adsorption capacity of the G/LDHs nanocomposites can be further enhanced by calcination at high temperature which eliminates the “memory effects” of parent LDHs [5,22]. Fang and Chen used the GO/LDHs nano-aerogel for the removal of methylene blue and Cd²⁺ from water. The aerogel exhibited high structural stability and a high number of active sites to capture Cd²⁺ ions. The hydrophilic surface of the aerogel helps retain the active sites in polar solvents [98]. Wen et al. used hybrids of MgAl LDHs with graphene synthesized by the hydrothermal route for the efficient removal of toxic As(V) from polluted water. The high Brunauer–Emmett–Teller (BET) surface area of these hybrids containing only 6.0 % of GO leads to an adsorptive capacity of 2.44 mmol/g [49]. In another study methyl orange was successfully adsorbed by rGO/NiCr from an aqueous solution containing organic matter, demonstrating its promise as an adsorbent for the removal of anionic dyes from wastewaters [99]. A few published studies on the application of G/LDHs nanocomposites for photocatalysis are also available. rGO/NiTi LDHs can be used for photocatalytic oxidation of water under visible light [55]. Lan et al. reported the degradation of rhodamine-B under visible light using the G/ZnCr LDHs with a remarkable photocatalytic activity (88% photodegradation of rhodamine after five regeneration cycles) [37]. The studies conducted by Miao et al. showed the superior catalytic activity and stability of rGO/NiAl LDHs as a support for Au nanoparticles in the selective oxidation of benzyl alcohol. The improved catalytic activity was attributed to the size of the Au nanoparticles and the number of basic sites on NiAl LDHs, while the defect sites and oxygen containing functional groups attached to rGO led to the catalytic stability [100]. Song et al. used G/CoAl LDHs for the hydrogenation of p-nitrophenol in

presence of excess sodium hydroxide and found excellent catalytic activity and stability [16]. These nanocomposites also reduces the emission of toxic CO and volatile organic compounds from the decomposition of the epoxy resin [101].

5.3.4 Nanofiller

These materials are promising nanofillers for polymers mainly to enhance the flame retardant characteristics. Good flame retardant properties of G/LDHs nanocomposites are attributed due to the complementary flame retardant properties of graphene and LDHs. Graphene is known to impart good flame retardant properties to polymers such as high density polyethylene, poly(methyl methacrylate) (PMMA), and polystyrene [2,28,102]. The flame retardant properties are due to the physical barrier formed by the layered structure of graphene which slows down the release of flammable gases, thus preventing the polymer matrix from burning [33,103]. On the other hand, LDHs are also used as flame retardants in polymer nanocomposites [104,105]. The LDHs helps to lower the temperature of the substrate by releasing H₂O and CO₂ produced during the burning process. The porous structure of the thermally decomposed products of LDHs can suppress smoke due to the large specific surface area [103]. However, the following major shortcomings restrict the use of bare graphene as a flame retardant: (1) homogeneous dispersion of graphene in the polymer matrix: and (2) relatively lower efficiency as a fire retardant, when bare graphene is used [106]. These shortcomings can be overcome by taking advantage of the synergic properties of LDHs and graphene [19]. Thermal stability of PMMA is reported to be improved by addition of rGO/NiAl LDHs. The heat release rate, smoke and carbon monoxide production rate of the resulting nanocomposites are relatively lower as compared to those of LDHs or rGO polymer

nanocomposites [33]. Wang et al. synthesized G/NiFe LDHs epoxy nanocomposites to reduce the fire hazards associated with the epoxy [18]. Incorporating 2% G/LDHs nanocomposites enhanced the degradation onset temperature of epoxy by 25 °C. Combustion and cone calorimetric data demonstrate a significant decrease in the peak heat release rate (PHRR) and the total heat release (THR) values of epoxy. The decrease in these parameters as compared to those of pure epoxy is an indication of the improvement in the flame retardant properties. Graphene retards the thermal degradation of the epoxy matrix via the adsorption and barrier effects, while LDHs increase the thermal oxidative resistance [18]. Recently, Huang et al. reported that the flame retardant properties of intumescent flame-retardant (IFR) PMMA nanocomposites improve significantly when G/LDHs nanomaterials are incorporated [103]. The authors have also reported 45% decrease in the PHRR for the PMMA/IFR/rGO/LDH nanocomposites, when filled with 10 wt. % IFRs, 1 wt. % graphene, and 5 wt. % LDHs [103].

Apart from imparting flame retardant properties, these nanomaterials can also be used as reinforced fillers in polymer nanocomposites. The LDHs hybrids with multi walled carbon nanotubes (MWCNTs) are also used as reinforced fillers in polymer nanocomposites [32,107]. Furthermore, these nanomaterials have been used as nanofillers in the development of silicon rubber nanocomposites with improved mechanical properties. The maximum increase in the tensile strength was achieved using 1 wt. % MgAl/MWCNTs LDHs, which resulted in a 134% increase in the tensile strength of the silicon rubber and better swelling behavior [108]. Chen et al. prepared poly(vinyl alcohol) hybrid films by orienting graphene and CoAl LDHs, which resulted in polymer

nanofilms with improved electrical conductivity [20]. However, an improved dispersion of the G/LDHs in polymers must be achieved.

5.3.5 Miscellaneous

Due to the conducting properties and capacitance of the G/LDHs nanocomposites, they have been used in sensing applications and medical diagnostics. G/NiAl LDHs along with hollow gold nanospheres have been used in the fabrication of an electrochemical immunosensor [38]. G/NiAl LDHs was also used in the detection of dopamine [24]. Non-enzymatic sensors are based on the direct electrocatalytic oxidation and typically use noble metal, metal oxide, metal hydroxide, and metal complexes along with the appropriate matrix [109]. Therefore, these G/LDHs nanocomposites can be used in biological sensing applications. For example, Fu et al. studied non-enzymatic glucose sensors based on ternary G/CNT/NiAl LDHs coated Gold (Au) nanoparticles [25]. The authors reported superior catalytic performance for oxidation of glucose with highly sensitive sensing of glucose even at lower concentration of glucose. These sensors also exhibited reproducibility, repeatability, stability and anti-interference characteristics. These characteristics were ascribed to the better conductivity and abundant active sites. In another study, G/ZnAl LDHs nanocomposites were used as a luminescent sensor for the detection of deoxyribonucleic acid (DNA) [23]. The nanocomposite can efficiently quench the emission of Ru(phen)₃Cl₂. A seventeen times enhancement of the luminescence was observed after the addition of DNA, which indicates that the luminescence enhancement and DNA count are directly proportional. The nanocomposite also helped in the luminescence recovery of the sensor. A hybrid 2D electrical-mechanical interface of G/MgAl LDHs has demonstrated a much stronger electro-

rheological results in a device with a quick response and low power consumption [46]. An electro-rheological suspensions exhibit electrically tunable rheology, mainly consisting of polarizable particles in electrically insulating oil, they are of great importance in applications such as electrical-mechanical interfaces for better controlling the device. These hybrid nanocomposites have also found applications in nickel plating. The G/NiAl LDHs nanocomposites have been successfully employed to recover nickel, phosphorous, and sulfur from a spent electrode-less nickel plating bath [110].

5.4 CONCLUSIONS AND PERSPECTIVES

Graphene hybridized layered double hydroxides (G/LDHs) are a valuable addition to the field of nanomaterials. They can be used as supercapacitors, sorbents, and heterogeneous catalysts because of their unique inherent properties. Their synthesis techniques, however, are delicate and sensitive, making it difficult to get a uniform size distribution in batch processes. The high surface area and the excellent thermal and catalytic stability make the G/LDHs nanocomposites a promising choice for catalysis. Superior capacitance properties of G/LDHs make them favorable materials for applications in supercapacitors. Furthermore, their pH responsive solubility, ability to form co-precipitates, and higher active sites make them capable for applications in highly selective extraction applications. The synergetic properties of hybrid material also contribute to enhance mechanical and fire retardant properties of polymer nanocomposites.

The synthesis and application of G/LDHs nanocomposites are new and emerging areas, worth further investigation for various applications that are not yet investigated in detail. For example, owing to their mesoporous structure and the potential of graphene to increase the molecular weight of polymers, these materials can be used as supports for

single site heterogeneous catalysts used in polymerization. Therefore, the use of G/LDH is expected to produce interesting results. The anisotropic properties and good dispersion ability make them suitable to be used as particulates in the dispersion phase of electro-responsive and electro-rheological fluids. The potential use of these materials in thin conducting films for applications in solar cells should also be investigated. Although these materials have been tested for the removal of contaminants from single component solutions in water, it is necessary to evaluate their performance in the removal of contaminants from multi-components solutions. Research on the use of these materials in sensing and drug delivery applications are rare. There are opportunities to investigate their potential in these areas in detail, taking into consideration their side effects and the toxicity of nanomaterials. Moreover, the potential use of these materials in the areas of biomedicine, nanoreactors, ion exchangers, and corrosion resistant coatings should also be studied. Establishing the structure property relationship of these materials is essential to understand the effects of various factors such as functionalization or doping of graphene. Finally, the challenges in obtaining material with precisely controlled particle sizes and morphology must be addressed.

Abstract

Hybrid nanofiller based on graphene and MgAl layered double hydroxides (G/LDHs) were synthesized successfully by co-precipitation method. The *in situ* polymerization technique was adopted using 1-hexene as comonomer, zirconocene as a catalyst and hybrid as drop-in nanofiller. An increase catalytic activity was recorded due to the addition of hybrid nanofiller. Further, a maximum catalytic activity was observed for nanofiller hybridized with 100 mg of graphene. However, higher graphene contents reduce the activity due to agglomeration process. Moreover, the degree of crystallinity (DOC) decreases due to the addition of short chain branching (SCB) in the copolymers. The thermal stability of the copolymers was analyzed using TGA. The activation energy E_A profiles thus obtained has revealed that the polymer nanocomposites having hybrid 100 mg of graphene have imparted higher thermal stability to the copolymers.

Keywords: Graphene, Layered double hydroxides, Hybrid materials, Polymer nanocomposites, Catalytic activity

6.1 INTRODUCTION

Recently, polymer nanocomposites have gained great interest due to their potential applications, especially in energy storage applications [1,2], supercapacitors [3–5], sensors [6–8], drug delivery [9,10], water purification [11,12] and food packaging [13]. Nanofillers efficiently dispersed and interact with the polymer matrix by attributing the polymer with high mechanical strength, thermal stability and enhanced electrical properties, depending on the nature of the filler [14,15]. Carbon based nanofillers especially; carbon nanotubes (CNTs) and graphene are mostly used nanofillers to prepare polymer nanocomposites [16,17]. Though, the high production cost and low dispersive index of CNTs have limited its use in polymer nanocomposites. On the contrary, graphene has a two dimensional (2D) monolayer carbon assembly, arranged in honeycomb structure with high surface area [17]. Thermal and mechanical properties of the polymers are dramatically enhanced even with low graphene contents [18]. However, the pristine graphene is not compatible with organic polymers and need to be functionalized or hybridized with the other 2D nanomaterials [9,19].

On the other hand, layered double hydroxides (LDHs) have 2D highly tunable brucite-like lamellar crystal structure [20]. Like graphene, LDHs are also employed as nanofillers for the synthesis of polymer nanocomposites [21]. These LDHs based polymer nanocomposites have shown better thermal stability and flame retardancy [22,23]. However, in order to maintain the properties inherited by the LDHs and uniform dispersion in the polymer matrices, the LDHs undergo anionic modification or hybridization with others 1D or 2D nanofillers [24,25].

Of particular, hybrid nanomaterials fabricated using LDHs and graphene (G/LDHs), is of great importance because of the superior intrinsic properties inherited by them due to the combination of the special properties of the parent materials [26,27]. G/LDHs nanofillers can be used in variety of applications due to their versatile properties and flexibility in the composition/preparation for fine-tuning [28]. These future generation nanomaterials have thus a great potential to be used as supercapacitors [29], nanofillers for polymer nanocomposites [30], medical applications [31] and hybrid sensors [32] *etc.* In addition, the polymer nanocomposites developed using G/LDHs nanofillers have shown significant improvement in mechanical, thermal and electrical properties [30].

Linear low density polyethylene (LLDPE) is an important resin of polyethylene (PE), synthesized by the copolymerization of ethylene with comonomers [33]. Because of their low production cost and promising properties, make them of great importance among the consumers [34]. The most prominent applications of LLDPE include food packaging, plastic bags and pipes *etc.* [35].

In the present study, G/LDHs hybrid nanofillers were successfully synthesized by co-precipitation method. Different ratios of composition/preparation of G/LDHs were obtained by varying the ultrasonicated graphene contents in the feed. The hybrid G/LDHs nanofillers were then employed for the *in-situ* copolymerization of the LLDPE based polymer nanocomposites, using metallocene/MAO as a catalyst/cocatalyst complex. G/LDHs nanofillers have a noteworthy effect on the catalytic activity, short chain branching (SCB) and thermal stability of the copolymers.

6.2 EXPERIMENTAL

6.2.1 Chemical Reagents

Bis(cyclopentadienyl zirconium (IV) dichloride) > 98 % ($C_{10}H_{10}Cl_2Zr$), Methylaluminoxane (MAO), Aluminum(III) nitrate nonahydrate [$Al(NO_3)_3 \cdot 9H_2O$], magnesium(II) nitrate hexahydrate [$Mg(NO_3)_2 \cdot 6H_2O$] and all other chemicals and solvents were provided by Sigma Aldrich Co. Graphene (96–99%, 50–100 nm) was purchased from Grafen Chemical Industries Co. (Turkey).

6.2.2 Preparation of MgAl LDHs

The standard co-precipitation method was adopted for the preparation of pure MgAl LDHs [36]. Briefly, precursor salts solution of both $Mg(NO_3)_2 \cdot 6H_2O$ (0.03M) and $Al(NO_3)_3 \cdot 9H_2O$ (0.01M) were initially well-mixed in 50mL of deionized (DI) water. Subsequently, the pH was adjusted at 10 ± 0.1 using 1M NaOH solution under vigorous stirring condition at 60 °C. After stabilizing the desired pH, the suspension was kept for reflux for 24h at 95 °C. The resultant white slurry was then centrifuge and washed with DI water and ethanol to remove any impurity. Lastly, the dense suspension was dried in vacuum oven at 60 °C for 24h. Approximately, 2.5 g of pure LDHs was synthesized with 3:1 molar ratio of precursor salts (Mg^{+2} : Al^{+3}).

6.2.3 Synthesis of Hybrid G/MgAl LDHs

The hybrids of G/MgAl LDHs were synthesized using co-precipitation method, already explained in our previous study [28]. Initially, graphene was ultrasonicated in 50ml solution of NaOH (0.20M) solution for 30min. Two different amounts of graphene were employed during this study i.e. 100 mg and 300 mg abbreviated as 100LDHs and

300LDHs respectively. The ultrasonicated graphene was then mixed with 3:1 molar precursor salt solution under continuous vigorous stirring. Consequently, the pH of the mixture was maintained at 10 ± 0.1 using 1M NaOH solution. The resultant hybrid solution was then kept for reflux at 95°C for 24h with subsequent centrifuging and washing. Finally the black dense suspension was dried in oven and characterized using different techniques. The weight percent of graphene were calculated to be 4 % and 12 % for 100LDHs and 300LDHs respectively from yield analysis.

6.2.4 *In-situ* polymerization

In-situ polymerization of ethylene-co-1-hexene was carried out in Schlenk reactor, according to the procedure, previously described in our work [37]. Briefly, the reactor was initially charged with 6mg (20 μ mol) of zirconocene catalyst, 75 mg of hybrid G/LDHs nanofiller, 1 mL of comonomer (1-hexene) and 100mL of solvent (toluene) under nitrogen environment, inside the glove box. The reactor was then connected to ethylene feed line (1.3 bar gauge pressure) and maintained at a temperature of 30 °C using oil bath and hot plate. Subsequently, 5ml of MAO was introduced to the reactor after 5min of saturation with ethylene. The reaction was then stopped after 30min of reaction time and quenched with acidified methanol under vigorous stirring. The polymerization product was then filtered and dried in oven for 12h at 60 °C. After drying, the polymer was weighted to calculate the activity, before subjected to other characterization steps. Four samples were synthesized using no-filler (control), pure LDHs, 100LDHs and 300LDHs represented by PC, PC-LDH, PC-100 and PC-300 respectively.

6.2.5 Characterizations

1. The purity and crystalline phases of the as-synthesized hybrid nanofillers were investigated using room temperature wide-angle XRD. The sampling were carried out using Mini-Flex XRD (from Rigaku) operated at 40 kV and 15 mA with CuK alpha radiation ($\lambda = 1.54060$). The diffraction angle was selected in the range of 5 to 70 degrees (2θ) at a scanning rate of 2 degree per minute.
2. Fourier transform infrared spectra (FT-IR) spectra of the G/LDHs nanofillers were recorded with a PerkinElmer FT-IR spectrometer (model 16F-PC) using KBr pellet technique in the range of 4000 to 400 cm^{-1} .
3. Surface morphology of the as-synthesized nanofillers was observed using TESCAN Lyra-3 Field Emission Dual Beam (Electron/Focused Ion Beam) system combined with high resolution field emission scanning electron microscope (FE-SEM).
4. The dispersion of graphene and structural analysis of the as-synthesized hybrid nanofillers were observed with JEOL, JEM-2100F (USA) Transmission electron microscope (TEM).
5. The melting and crystallization behavior of the polymer nanocomposites were investigated using differential scanning calorimetry (DSC Q-1000) TA instrument using third heating cycle (30° to 160 °C).
6. Thermo-gravimetric analysis (TGA) was performed to study the thermal stability of the as-synthesized polymer nanocomposites. SDT-Q600 TGA by TA instruments was utilized at three different heating rates i.e. 10, 15, and 20 °C/min.

7. Crystallization analysis fractionation (CRYSTAF) supplied by Polymer Char (model-200) was employed to find the micro-structure and chemical composition distribution (CCD) of the polymer nanocomposites. Initially, the samples were dissolved in 1, 2, 4 trichlorobenzene (0.1 mg/mL), with subsequent cooling at 0.1 °C /min, with built-in infrared sensor detecting the crystallized portion of the polymer.

8. To find the comonomer incorporation analysis, ¹³C nuclear magnetic resonance (¹³C NMR) was conducted. ASTM method 5017-96 [38], based on integration of peaks relative to main methylene resonance at 30.0 ppm on x-axis was employed to compute the effect of nanofiller on the comonomer incorporation.

6.3 Results and Discussion

6.3.1 Establishment of hybrid G/LDHs nanofillers

XRD Patterns

XRD patterns of pure MgAl LDHs, pristine graphene (PG), 100LDHs and 300LDHs are depicted in Figure 6-1. The PG has shown an intense crystalline characteristic peak around $2\theta \approx 26^\circ$ which corresponds to C(002) plane obtained from graphene reflection [39]. Moreover, the sharp diffraction peaks inherited by pure LDHs, 100LDHs and 300LDHs indicate their good lamellar structure and high crystalline nature. The diffraction peaks are approximately at ($2\theta \approx$) 11° , 23° , 35° , 39° , 60° and 62° which relates to the (003), (006), (009), (012), (110) and (113) crystal structure planes respectively, and is in consistent with the reported data [40,41]. As expected, the pure MgAl LDHs had more intense peaks at (003) and (006) planes compared to 100LDHs and 300LDHs. Moreover, at higher contents of graphene in the sample corresponds to intense (002) peak

(See Figure 6-1d). Furthermore, the XRD patterns have concluded that the G/LDHs hybrid nanofillers are less crystalline in nature than pure LDHs. In addition, the width of the XRD spectral peaks increases with the addition of graphene compared to pure LDHs [42]. Notably, the consistent appearance of (110) and (113) planes of almost same intensity has confirmed the well maintain crystal structure of LDHs [43,44].

Figure 6-1. XRD patterns of (a) MgAl LDHs (b) PG (c) 100LDHs (d) 300LDHs

FT-IR Spectroscopy

The FT-IR spectra for pure LDHs, PG, 100LDH and 300LDH are presented in Figure 6-2. The characteristic peaks for the LDHs have shown a broad band at 3470 cm^{-1} which is due to the stretching vibration of hydrogen bonding and intercalated traces of water molecules that comes from synthesis process. Whereas, the weak band at peak position 1630 cm^{-1} is representing the bending modes of these intercalated water molecules [25]. Furthermore, the stretching vibration of the interlayer anions (NO_3^{-}) of MgAl LDHs (1384 cm^{-1}) and metal-oxygen metal ($400\text{-}810\text{ cm}^{-1}$) are consistent with the reported data [45]. The PG absorption spectrum (See Figure 6-2) shows two weak band regions i.e. at position $\approx 1608\text{ cm}^{-1}$ (due to skeleton vibration of the graphene nanosheets) and ≈ 3423 (due to structural -OH groups and vibration of water molecules) [39].

Figure 6-2. FT-IR spectra of (a) MgAl LDHs (b) PG (c) 100LDHs (d) 300LDHs

FE-SEM analysis

In order to study the morphology and microstructure of the hybrid nanofillers, PG, pure LDHs, 100LDs and 300LDHs were characterized using FE-SEM (See Figure 6-3). As expected, the PG is found to exist as smooth flat nanosheets, whereas, the occurrence of LDHs are as aggregates. The FE-SEM images for pure LDHs have revealed their lamellar surface morphology, stacked on top of each other. The hybrid images clearly indicated the synergy of graphene nanosheets inside the layered structure of LDHs.

Figure 6-3. FE-SEM images of (a) MgAl LDHs (b) PG (c) 100LDHs (c) 300LDHs

TEM analysis

TEM images of PG, pure LDHs, 100LDHs and 300LDHs are displayed in Figure 6-4. The customary hexagonal nanoscale platelet structure of LDHs can be clearly seen from HR-TEM images. Further, the hexagons are stacked and strongly adhere to each other [41]. The hybrid G/LDHs shows homogeneous dispersion of graphene inside the nanofiller and a synergistic effect is observed in Figure 6-4 (c, d).

6.3.2 Characterization of LLDPE-G/LDHs nanocomposites

Catalytic activity

The activity of the catalyst was calculated from the obtained yield and the corresponding polymerization results are summarized in Table 6-1. The addition of these nanofillers significantly influences the catalytic activities. The PC-LDHs has shown better catalytic activity (See Table 6-1) compared to control polymer sample (PC). Since, LDHs provide easier access to the active sites of the metallocene catalyst with relatively less agglomerated and spherical polymer particles. Moreover, the LDHs supported metallocene catalysts has shown more stability and higher catalytic activity towards ethylene polymerization [46]. The PC-100LDHs has maximum yield compared to all ethylene-co-1-hexene copolymers under study. This increase in activity is due to the hybridization of LDHs with 100 mg of graphene. The high surface area provided by 100LDHs hybrid nanofillers compared to pure LDHs, enables ethylene monomers with an easy access towards the active sites of zirconocene catalyst. However, further addition of graphene causes agglomeration around the catalyst, which reduces the active sites availability and thus causing decrease in the activity of zirconocene [47]. This phenomena is termed as “steric hindrance” [15]. Thus PC-300LDHs has relatively less catalytic activity than PC-100LDHs. However, minimal effects in molecular weights of the as-synthesized copolymers were observed due to the filler addition.

Table 6-1. Effect of hybrid G/LDHs nanofillers on the catalytic activity and other properties of LLDPE nanocomposites

S/no.	Sample code	Filler type/Amount (mg)	Activity ^a	DOC ^b	T_m ^c	M_w ^d
			(kg PE mole ⁻¹ hr ⁻¹ bar ⁻¹)		(°C)	(g/mol)
1	PC (control)	No filler	246.03 ± 3.29	39.02	122.27	22,141
2	PC-LDHs	Pure LDHs/75	299.83 ± 4.33	34.46	116.36	19,266
3	PC-100LDHs	100LDHs/75	389.67 ± 7.49	32.93	114.33	20,944
4	PC-300LDHs	300LDHs/75	362.20 ± 2.50	29.88	116.79	22,748

Reaction Temperature = 30 °C; solvent used= toluene (100 mL); zirconocene amount = 6 mg (20 μmol); comonomer used = 1-hexene (1 mL); polymerization time = 30 min

Crystallinity and 1-hexene incorporation

The degrees of crystallinity (DOC) of the copolymers were greatly influenced due to nanofiller addition (See Table 6-1). CRYSTAF is being utilized to figure out the CCD of the as-synthesized polymer nanocomposites, as depicted in Figure 6-5. As observed that a much wider profiles are obtained for the polymer nanocomposites compared to the PC (control). This change occurred in CCD and microstructure of the polymer samples were due to SCB (1-hexene incorporation), that were being induced by the nanofiller. In case of LLPDE, the comonomer incorporation has a very obvious effect on the DOC. Higher 1-hexene incorporation leads to lower DOC and vice versa [37]. The peak crystallization temperature (T_{peak}) obtained from CRYSTAF results are tabulated in Table 6-2. The decrease in T_{peak} temperatures indicates that nanofiller inducing more SCB to the polymer backbone thus decreasing the DOC. The CRYSTAF results were validated by ^{13}C NMR analysis (See Table 6-2). The maximum 1-hexene incorporation was recorded for PC-300LDHs, indicating more SCB added to the backbone structure of PE. On the other hand the melting temperatures (T_m) were also affected by SCB. A decrease in T_m was recorded for higher 1-hexene incorporation. However, a slight increase in T_m for PC-300LDHs nanocomposites was observed due to the presence of higher graphene contents.

Figure 6-5. CRYSTAF profiles of LLDPE-hybrid G/LDHs polymer nanocomposites

Table 6-2. Effect of hybrid nanofillers on CRYSTAF curves

Sample ID	PC	PC-LDHs	PC-100LDHs	PC-300LDHs
T _{Peak} (°C)	78.2	73.4	73	71.1
1-hexene incorporation (¹³ C NMR)	3.30	5.1	5.3	5.8

Thermal Stability

The TGA curves of all the samples are shown in Figure 6-6 at 10 °C /min and the selected results are listed in Table 6-3. The degradation curve is shifted to the right i.e. increasing temperature with the addition of the nano-filler. For example the, temperature at 5 wt. % (T5%) loss is increased from 379 °C for neat polymer to 397 °C for PC-LDH nanocomposites. Similarly, for the PC-100LDHs the T5% increased to 414 °C, the highest in this case. The T5% for PC-300LDHs is observed to be slightly lower than that of PC-100LDHs i.e. 409 °C. This can be due to higher SCB as well as the high content of graphene within the hybrid nanofillers, which can increase the thermal conductivity of the nanocomposites, consequently providing better heat conduction and relatively faster degradation. The increase in the T5% indicates the nanocomposites are thermally more stable as compared to the neat polymer. A similar increasing trend for T50% and peak decomposition temperature (T_p) is also observed. However, the difference for T50% and T_p between the neat polymer and nanocomposites is reduced as compared to the T5%. The higher thermal stability of the nanocomposites, especially in the initial stages can be attributed to the layered structure and gas barrier characteristics of the nanofillers, which inhibits the evolution of the combustion gases [15,45]. Figure 6-7 shows the derivative of weight loss against temperature for all the samples.

Figure 6-6. Weight loss with temperature ramp at 10 °C /min for polymer and its nanocomposites

Figure 6-7. Derivative of weight loss with temperature ramp at 10 °C/min for polymer and its nanocomposites

Table 6-3. TGA analysis results for polymer and the nanocomposites at 10 °C/min

Sample	$T_{5\%}$ (°C)	$T_{50\%}$ (°C)	T_p (°C)
PC	379	464	474
PC-LDHs	397	468	476
PC-100LDHs	414	471	479
PC-300LDHs	409	470	478

A further insight of the thermal degradation was analyzed by calculating the apparent activation energy of degradation. As already reported in literature that the degradation of PE is a complex process i.e. it involves multiple kinetics steps [46]. Therefore, we have use iso-conversional Friedman method for the calculation of activation energy. Friedman method given by equation1, is an accurate differential method and provides the correct values of activation energy even if it is conversion dependent [47,48]. For this purpose each sample was heated with three heating rates 5, 10, and 15 °C /min under nitrogen flow of 100 mL/min.

$$\ln \left(\beta_i \left(\frac{d\alpha}{dT} \right) \right)_{\alpha_j} = - \left[\ln f(\alpha) + \frac{E_A}{RT_i} \right] \quad (1)$$

Whereas, β is the heating rate, α is the fractional conversion, E_A is the activation energy, R is gas constant and T is the temperature corresponding to the fractional conversion. E_A at specific values of α can be calculated from the slope of the straight line of $\beta_i \left(\frac{d\alpha}{dT} \right)$ vs $\frac{1}{RT_i}$, whereas, i represents the heating rate. Figure 6-8 shows the activation energy for all samples as a function of α . It can be observed that for all the samples the E_A changes with α , indicating a multiple step degradation mechanism. The degradation of polyethylene is known to start at the weak link by the reaction of a radical with the hydrogen atom on the fifth carbon atom. This free radical then degrades into either propene or 1-hexene. The initial lower values of the E_A correspond to this starting initiation reaction at the weak links. Later on, the degradation process is governed by the random scission process which demands a comparatively higher E_A [46]. As it can be seen from Figure 6-8 (a-d), the initial values of E_A increased with the addition of the nanofiller, from around 155 for PC to 169, 186, and 216, (kJ/mol) for PC-LDHs, PC-100LDHs, and

PC-300LDHs respectively. This increase can be attributed to higher thermal stability due to the addition of nanofillers. For the PC-300LDHs nanocomposites, average E_A is slightly lower as compared to the PC-100LDHs; this is due to the higher SCB content of the former, which provides more favorable links for the degradation to occur.

Figure 6-8. E_A as a function of the fractional conversion for (a) PC, (b) PC-LDHs, (c) PC-100LDHs, and (d) PC-300LDHs

6.4 Conclusion

Hybrid G/LDHs nanofillers were used for the synthesis of LLDPE nanocomposites. High catalytic activities and lower DOC were recorded for the as-synthesized polymer nanocomposites due to the nanofiller addition. 1-hexene incorporation was also increased due to more SCB in the polymer matrix. The PC-100LDHs nanocomposites have maximum catalytic activity (Approx. 36 % increased). A slight increase in the T_m of the PC-300LDHs was attributed due to presence of high graphene contents. Activation Energy (E_A) for the as-synthesized polymer nanocomposites were calculated using iso-conversional Friedman method. A higher average E_A was obtained for PC-100LDHs (≈ 270 kJ/mol), indicating its higher thermal stability. Moreover, the improvements observed in catalytic activity, comonomer incorporation and thermal properties of these polymer nanocomposites, indicating better dispersion of nanofillers in the polymer matrix

CHAPTER 7

CONCLUSIONS AND RECOMMENDATIONS

7.1 Conclusion

The *in-situ* polymerization of ethylene-co- α -olefin were carried out in slurry phase polymerization using zirconocene complex and Schlenk techniques. These α -olefin (comonomers) significantly influenced the catalytic activity, melt crystallization and lamellar thickness distribution. Approx. 18 %, 19 % and 15 % increased catalytic activities were recorded with the addition of just 1 mL of 1-hexene, 1-octene and 1-decene comonomers respectively. Mo-model successfully covered the melt crystallization behavior of copolymers used under this study. The activation energies (E_A), calculated for the fabricated copolymers has shown that the crystallization behavior is more affected by comonomer contents rather than its type for same feed ratios.

The drop in nanofiller (TiO_2/Mn) significantly increased the catalytic activity (approx. \approx 44 %) for ethylene-co-1-hexene at an optimum dose of 15 mg. The filler also increased the 1-hexene incorporation by imparting more SCB to the polymer structure and hence decreased the DOC and T_m . An increased E_A was recorded for the as-synthesized LLDPE nanocomposites, which indicates slow crystal growth rate in the presence of nanofiller.

G/LDHs hybrid nanofillers were synthesized in house by co-precipitation route. The hybrid fillers were then used as a drop in filler during *in-situ* ethylene polymerization in the presence of 1-hexene as a comonomer. The polymer nanocomposites synthesized

with 100 mg of hybridized graphene and LDHs have shown maximum catalytic activity (approx. 36% increased) and is more thermally stable ($E_A \approx 270$ kJ/mol) compared to the control ethylene-co-1-hexene copolymer ($E_A \approx 155$ kJ/mol).

The research outcomes are four ISI indexed (peer reviewed) research publications. The details of these manuscripts are as under:

7.2 Future Recommendations

- The effect of different crystallite sizes of nano titania can be studied for the activity of zirconocene catalyst.
- The work can be extended to study the effect of hybrid nanofillers on the mechanical properties of the LLDPE nanocomposites.
- More combination of hybrid nanofillers should be synthesized and employed as a drop in nanofillers for the production of LLDPE nanocomposites.
- It is recommended to used LDHs as support material for zirconocene catalyst.
- It is highly recommended to synthesized Mn based hybrid nanofillers for LLDPE nanocomposites.

Vitae

MUHAMMAD DAUD

Department of Chemical Engineering,
King Fahd University of Petroleum & Minerals,
Dhahran, Kingdom of Saudi Arabia

Phone (M): +966-598902558

Phone (M): +92-3459111772

Nationality: Pakistani

Date of birth: 23-05-1983

Email: daud@uetpeshawar.edu.pk

EDUCATION

Ph.D : Chemical Engineering, 2012-2016

King Fahd University of Petroleum & Minerals, Saudi Arabia

Thesis: Effect of Nano Fillers on the Production and Properties of LLDPE using *in-situ* Polymerization

M.Sc : Advance Chemical Engineering

University of Engineering & Technology, Peshawar, Pakistan

Thesis: Coal Briquettes Analysis Using Different Binding Materials, For Khyber Pakhtunkhwa Coal

B.Sc.: Chemical Engineering (Gold Medalist), 2004-2007

University of Engineering & Technology, Peshawar, Pakistan

RESEARCH INTERESTS

- Polymer Synthesis
- Crystallization Kinetics
- Solid State Kinetics
- Nanocomposites

TEACHING INTERESTS

- Transport Phenomena
- Reaction Engineering
- Simultaneous Heat and Mass Transfer
- Polymer Material Testing and Characterization

PROFESSIONAL EXPERIENCE

- Lecturer, Department of Chemical Engineering, UET Peshawar, from 13th December, 2007 till date (on study leave).
- Lecturer-B, Department of Chemical Engineering KFUPM, KSA from January 2012 December 2016.
